## Volume Two: Health, Disease and Therapeutics

---

### FIFTH EDITION

*Edited by*

MARTIN HEWISON

*Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, United Kingdom*

ROGER BOUILLON

*Professor in Endocrinology, University Hospital, Catholic University of Leuven (K.U. Leuven), Leuven, Belgium*

EDWARD GIOVANNUCCI

*Harvard TH Chan School of Public Health, Boston, MA, United States*

DAVID GOLTZMAN

*Departments of Medicine and Physiology, McGill University, and Endocrine Division,  
McGill University Health Centre, Montreal, QC, Canada*

MARK MEYER

*Department of Nutritional Sciences, University of Wisconsin-Madison, Madison, WI, United States*

JOELLEN WELSH

*Cancer Research Center, University at Albany, Albany, NY, United States*

**ACADEMIC PRESS**

*An imprint of Elsevier*

### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

## VOLUME I

### 1. Book introduction: Major trends in vitamin D research

DAVID FELDMAN AND J. WESLEY PIKE

1. History of the <i>Vitamin D</i> book	1
2. Major trends in the vitamin D field	1
3. Mechanism of action	2
4. Mutations in the VDR and critical metabolic enzymes cause childhood rickets	3
5. Vitamin D assays	4
6. Extra-skeletal actions	4
7. Population studies and clinical trials	4
8. Controversy: what constitutes normal or adequate concentrations of vitamin D?	5
9. Vitamin D and autoimmune disease	5
10. Vitamin D and COVID-19	5
11. Vitamin D and cancer	5
12. Is vitamin D useful for the prevention or treatment of colorectal cancer?	6
13. Closing comments with thanks and appreciation to the many authors, the critical Elsevier staff, and the many readers that made this undertaking possible	7

References

### 2. Evolution of human skin pigmentation and vitamin D

NINA G. JABLONSKI

1. Introduction	9
2. The solar context of human skin color evolution	10
3. The nature of the selective factors leading to the evolution of skin pigmentation in early <i>Homo</i>	11
4. Folate conservation and the evolution of permanent protective pigmentation	12
5. Early hominin dispersal out of the tropics and vitamin D production	12

6. The evolution of skin pigmentation in <i>Homo sapiens</i>	16
7. The effects of cultural buffering, rapid migrations, and modern lifestyles on skin color and vitamin D	19
8. Summary points	20
References	21
Further reading	25

### 3. Photobiology of vitamin D

MICHAEL F. HOLICK AND  
ANDRZEJ T. SLOMINSKI

1. Introduction	27
2. Historical perspective	28
3. Photobiology of vitamin D	29
4. Role of sunlight and dietary vitamin D in bone health, overall health, and well-being	33
5. Ultraviolet devices for producing vitamin D	34
6. Alternative pathways generating noncanonical active forms of vitamin D and their photoderivatives	35
7. Sunlight, vitamin D, and skin cancer	36
8. Conclusions	37
9. Summary points	39
Acknowledgment	39
References	39
Further reading	45

### 4. The activating enzymes of vitamin D metabolism (25- and 1 $\alpha$ -hydroxylases)

GLENNVILLE JONES, DAVID E. PROSSER, AND  
MARTIN KAUFMANN

1. Introduction	47
2. General information regarding vitamin D hydroxylases	49
3. Vitamin D <sub>3</sub> -25-hydroxylases	49
4. 25-Hydroxyvitamin D-1 $\alpha$ -hydroxylase	57
5. Additional topics	60
6. Conclusions	64
7. Summary points	64
References	65
Further reading	69

## 5. CYP24A1: structure, function, and physiological role

RENÉ ST-ARNAUD AND GLENVILLE JONES

1. Introduction	71
2. CYP24A1-catalyzed pathways	71
3. C24-oxidation pathway	72
4. C23-hydroxylation pathway	73
5. CYP24A1, a multifunctional enzyme	73
6. Biological relevance of the C24-oxidation pathway	74
7. Structure—function relationships	74
8. Mutations of CYP24A1 in infantile hypercalcemia type 1	76
9. Preclinical models of infantile hypercalcemia type 1	77
10. CYP24A1 involvement in other systems	77
11. 24,25(OH) <sub>2</sub> D <sub>3</sub> and chondrocyte maturation	77
12. 24,25(OH) <sub>2</sub> D <sub>3</sub> and fracture repair	78
13. Conclusions	79
14. Summary points	80
References	80

## 6. Alternative pathways for vitamin D metabolism

ANDRZEJ T. SLOMINSKI, ROBERT C. TUCKEY, CARL JENKINSON, WEI LI, AND ANTON M. JETTEN

1. Introduction	85
2. Cytochrome P450 <sub>scc</sub> (CYP11A1): an overview	86
3. Introduction to the skin in a photobiology context	86
4. CYP11A1 mediated metabolism of 7DHC with local and systemic implications	88
5. CYP11A1-mediated metabolism of vitamin D	88
6. Enzymatic activation of lumisterol and tachysterol	92
7. Phenotypic activity of CYP11A1-derived hydroxyderivatives and their mechanism of action	92
8. C3-epimerization of vitamin D metabolites	97
9. Phase II conjugation of vitamin D metabolites	99
10. Conclusions	103
11. Summary points	103
Acknowledgment	103
References	103

## 7. Vitamin D—binding protein

ROGER BOUILLON, RENE F. CHUN, AND FRANS SCHUIT

1. Introduction	111
2. Vitamin D-binding protein: gene and protein structure	112
3. Functions of vitamin D—binding protein	118
4. The vitamin D—binding protein—actin complex	126

5. DBP binds fatty acids	128
6. The role of vitamin D—binding protein in inflammatory processes and in the immune system	128
7. Conclusions	129
8. Summary points	130
References	130

## 8. Regulation of renal vitamin D metabolism

MARK B. MEYER, NANCY A. BENKUSKY, SEONG MIN LEE, AND J. WESLEY PIKE

1. Introduction	139
2. Major physiologic regulators of renal vitamin D metabolism	140
3. Genomic structure and deletion of the <i>CYP27B1</i> and <i>CYP24A1</i> genes	141
4. Genomic mechanisms for <i>CYP27B1</i> regulation	142
5. Genomic mechanisms for <i>CYP24A1</i> regulation	148
6. Conclusions	149
7. Summary points	151
Acknowledgments	151
References	151

## 9. Regulation of extra-renal synthesis of 1,25(OH)<sub>2</sub>D

MARTIN HEWISON AND JOHN S. ADAMS

1. Introduction	155
2. 1 $\alpha$ -OHase and the <i>CYP27B1</i> gene	156
3. Macrophage 1 $\alpha$ -OHase	157
4. Macrophage 1 $\alpha$ -OHase and responsiveness to immune cell regulators	161
5. Molecular mechanisms for regulation of extrarenal 1 $\alpha$ -OHase	164
6. 1 $\alpha$ -OHase in cells other than macrophages	167
7. Dysregulated synthesis of 1,25(OH) <sub>2</sub> D and human disease	173
8. Conclusions and future prospects	176
9. Summary points	178
References	178

## 10. Structural basis for ligand activity in vitamin D receptor

ANNA Y. BELORUSOVA AND NATACHA ROCHEL

1. Introduction	189
2. Conclusions and perspectives	207
3. Summary points	207
References	208

## 11. Genome-wide perspectives on vitamin D receptor actions

J. WESLEY PIKE, SEONG MIN LEE, NANCY A. BENKUSKY, AND MARK B. MEYER

1. Introduction	213
-----------------	-----

2. Target genes involved in the regulation of mineral metabolism	213	7. Interplay between FoxO proteins and the VDR	247
3. The production of 1,25(OH) <sub>2</sub> D <sub>3</sub> in diverse nonrenal target cells	214	8. Vitamin D signaling regulates the function of the oncogenic transcription factor c-MYC	249
4. Transcriptional mechanism of action of 1,25(OH) <sub>2</sub> D <sub>3</sub>	214	9. Widespread crosstalk between NF-κB and vitamin D signaling	251
5. New insights into transcriptional activation of vitamin D	216	10. Insights into VDR-dependent transcriptional regulation from genomics studies	252
6. Current advances in transcriptional regulation	218	11. Conclusions	253
7. Analogs of vitamin D	218	12. Summary points	253
8. Pharmacology of vitamin D analogs	219	References	253
9. Recent possibilities for enhancing vitamin D analog SAR potential	220	Further reading	259
10. Highlights of transcriptional mechanisms	220		
11. Returning to vitamin D analogs—a new analytical approach	224	<b>14. Vitamin D and microRNAs</b>	
12. Conclusions	224	HENGGUANG ZHAO, MARIANELA FORCELLATI, DAMIEN BUSCHITTARI, JOHN E. HECKEL, CHRISTOPHER J. MACHADO, SRI RAMULU N. PULLAGURA, AND THOMAS S. LISSE	
13. Summary points	224		
Acknowledgments	225	1. Introduction	261
References	225	2. MicroRNAs: the posttranscriptional age	263
		3. Complexity of miRNA regulation, biogenesis, and posttranscriptional regulatory functions	263
<b>12. Vitamin D, chromatin, and epigenetics</b>		4. Nuclear receptors and miRNAs	266
CARSTEN CARLBERG		5. The relationship between miRNAs and the vitamin D synthesis, metabolism, and signaling systems	267
1. Introduction	229	6. Interplay between vitamin D and miRNAs in biological systems	274
2. The impact of chromatin	230	7. Translational aspects of miRNAs	281
3. The impact of epigenetics	231	8. Strategies for miRNA and target identification for vitamin D research	282
4. The nuclear receptor superfamily member VDR	232	9. Conclusions	284
5. Genome-wide location of VDR-binding sites	232	10. Summary points	284
6. CTCF as organizer of vitamin D-dependent chromatin domains	234	Acknowledgments	284
7. Vitamin D-triggered epigenetic changes	234	References	284
8. A chromatin model of vitamin D signaling emerges	235		
9. Epigenetic effects of vitamin D in vivo	235	<b>15. Pathway based-analysis of transcriptomic data from vitamin D studies</b>	
10. Conclusion	237	CHRIS T.A. EVELO AND SUSAN L.M. COORT	
11. Summary points	237		
References	237	1. Introduction	291
Further reading	239	2. Transcriptomic data	291
		3. Vitamin D <sub>3</sub> -related pathways in online pathway databases	291
<b>13. The diverse genomic mechanisms of action of the vitamin D receptor</b>		4. Workflow pathway-based analysis for transcriptomic data	293
JOHN H. WHITE, FATEMEH SARMADI, AND PATRICIO ARTUSA		5. The six steps in the pathway-based analysis workflow of transcriptomic data	293
1. Overview	241	6. Example case—immunometabolic effect of vitamin D <sub>3</sub> in dendritic cells and monocytes	296
2. The VDR and the hairless repressor: regulation of transcription in the absence of 1,25(OH) <sub>2</sub> D	242	7. Conclusion	297
3. Crosstalk between the VDR and TGF-β signaling	243	8. Summary points	298
4. The VDR and the AP-1 family of transcription factors	244	References	298
5. JAK/STAT signaling and the VDR in immunity	244		
6. Wnt signaling and the VDR: evidence for cancer prevention	245		

## 16. Vitamin D and the kidney

KITTRAWE KKRITMETAPAK, PETER J. TEBBEN, AND  
RAJIV KUMAR

1. Introduction	301
2. Calcium handling by the kidney	302
3. Phosphate handling by the kidney	303
4. Role of the kidney in the metabolism of 25(OH)D	303
5. Effects of vitamin D, 25(OH)D, and 1,25(OH) <sub>2</sub> D on the renal handling of calcium and phosphate	307
6. Distribution and regulation of vitamin D-dependent proteins in the kidney	310
7. Mechanisms of altered vitamin D metabolism in kidney disease	318
8. Conclusion	319
9. Summary points	320
References	320

## 17. Vitamin D and the calcium-sensing receptor

CHIA-LING TU AND WENHAN CHANG

1. Introduction	331
2. Development of the parathyroid glands	332
3. The parathyroid hormone gene	332
4. The calcium-sensing receptor	332
5. Overview of systemic Ca <sup>2+</sup> homeostasis	340
6. Actions of CaSR and VDR in tissues uninvolved in extracellular Ca <sup>2+</sup> homeostasis	350
7. Summary points	352
References	353
Further reading	363

## 18. Regulation of intestinal calcium and phosphate absorption by vitamin D

JAMES C. FLEET, SYLVIA CHRISTAKOS, AND  
HENG JIANG

1. Introduction	365
2. Intestinal calcium absorption	365
3. Molecular models of calcium absorption	368
4. Physiologic regulation of vitamin D-mediated intestinal calcium absorption	371
5. Genomic and genetic studies of vitamin D-regulated intestinal calcium absorption	374
6. Conclusions regarding the role of vitamin D on intestinal calcium absorption	375
7. An overview of intestinal phosphate absorption	375
8. Conclusion regarding the role of vitamin D on phosphate absorption	378
9. Summary points	378
References	378
Further reading	383

## 19. Vitamin D and FGF23

NEJLA LATIC AND REINHOLD G. ERBEN

1. Introduction	385
2. FGF23 signaling	386
3. Role of vitamin D signaling in the regulation of FGF23 production	387
4. Regulation of renal 1,25(OH) <sub>2</sub> D production by FGF23	388
5. Role of FGF23-mediated regulation of vitamin D metabolism in health and disease	390
6. Conclusion	391
7. Summary points	391
References	391

## 20. Osteoclastogenesis and vitamin D

YUKO NAKAMICHI,  
NAOYUKI TAKAHASHI, TATSUO SUDA, AND  
NOBUYUKI UDAGAWA

1. Introduction	395
2. Regulation of mineral metabolism by vitamin D, parathyroid hormone, and fibroblast growth factor 23	396
3. Phenotypes of vitamin D receptor knockout mice	398
4. Osteoclast lineage-specific vitamin D receptor knockout mice	400
5. Regulation of osteoclastogenesis by the receptor activator of nuclear factor- $\kappa$ B ligand/receptor activator of nuclear factor- $\kappa$ B/osteoprotegerin system	400
6. In Vitro regulation of osteoclastogenesis by vitamin D	401
7. In Vivo regulation of osteoclastogenesis by vitamin D	401
8. Conclusion	405
9. Summary points	405
References	406
Further reading	408

## 21. Vitamin D activity in osteoblasts and osteocytes

PAUL H. ANDERSON

1. Introduction	409
2. Properties of osteoblasts and osteocytes	409
3. The local and endocrine effects of 1,25(OH) <sub>2</sub> D <sub>3</sub> on osteoblast and osteocyte function	412
4. Conclusion	415
5. Summary points	415
References	415
Further reading	418

## 22. Cartilage

BARBARA D. BOYAN, NIELS C. ASMUSSEN,  
MARYAM DOROUDI, KAYLA M. SCOTT, AND  
ZVI SCHWARTZ

1. Introduction	419
2. Properties of cartilage tissues	420
3. Regulation by vitamin D	420
4. Conclusion	429
5. Summary points	430
References	430
Further reading	434

## 23. Vitamin D and bone: an integrated approach

LIEVE VERLINDEN AND GEERT CARMELIET

1. Introduction: a link between bone metabolism, calcium homeostasis, and $1,25(\text{OH})_2\text{D}_3$ activity	435
2. $1,25(\text{OH})_2\text{D}_3$ and bone metabolism during a positive calcium balance	436
3. Negative calcium balance resulting from insufficient vitamin D action	441
4. Negative calcium balance with sufficient vitamin D	444
5. Vitamin D and FGF23	446
6. Conclusion	447
7. Summary points	448
References	448
Further reading	452

## 24. Vitamin D in dentoalveolar and oral health

BRIAN L. FOSTER, EMILY Y. CHU, AND  
PHILIPPE P. HUJOEL

1. Introduction	453
2. A brief primer on dentoalveolar cells and tissues	453
3. Vitamin D metabolism and mechanisms of action on dental cells	458
4. Vitamin D, rickets, and the oral tissues	460
5. Hereditary vitamin D-related diseases affecting dentoalveolar tissues	463
6. Other inherited rachitic conditions affecting vitamin D metabolism	467
7. Vitamin D and oral health	471
8. Conclusions	474
9. Summary points	475
Acknowledgments	475
References	475
Further reading	484

## 25. Role of vitamin D in skin and hair biology

DANIEL D. BIKLE AND MARIE B. DEMAY

1. Introduction	485
2. Cutaneous production of vitamin D and its biologically active metabolites	486
3. Regulation of keratinocyte differentiation	488
4. Role of vitamin D signaling in skin cancer	496
5. Role of vitamin D signaling in epidermal wound repair	498
6. Role of vitamin D signaling in hair follicle cycling	498
7. Summary points	502
References	502

## 26. Vitamin D and the cardiovascular system

ADRIANA DUSSO, KEVIN T. BAUERLE, AND  
CARLOS BERNAL-MIZRACHI

1. Introduction	511
2. Vascular physiology	512
3. Identification of the VDR in the vascular system	512
4. Vascular relaxation	513
5. Structural vascular changes	515
6. Vascular inflammation	516
7. Angiogenesis	518
8. Blood coagulation and fibrinolysis	520
9. Animal models	520
10. Clinical studies in cardiovascular disease	524
11. Conclusion	527
12. Summary points	528
References	528
Further reading	535

## 27. Vitamin D, brain development and function

DARRYL EYLES, XIAOYING CUI, AND JOHN J. MCGRATH

1. Introduction	537
2. Vitamin D signaling in the brain	538
3. Dietary vitamin D deficiency, effect on brain development, and function	540
4. Vitamin D regulates essential processes in normal brain development	546
5. Possible neuroprotective mechanisms of vitamin D in the developing brain	549
6. Developmental vitamin D deficiency and neuropsychiatric disorders	551
7. Vitamin D supplementation and neurodevelopmental outcomes	553
8. Conclusions	554
9. Summary points	554
References	555

## 28. Vitamin D, VDR, and adipose tissue: focus on cellular mechanisms

CARMEN J. NARVAEZ AND JOELLEN WELSH

1. Introduction	563
2. Storage of vitamin D metabolites in adipose tissue	564
3. Effects of 1,25(OH) <sub>2</sub> D on adipogenesis at the cellular level	566
4. Effect of 1,25(OH) <sub>2</sub> D on human mesenchymal precursors	571
5. Vitamin D receptor regulation of thermogenesis in cell systems	573
6. Impact of vitamin D signaling on adiposity in mouse models	574
7. Effect of vitamin D deficiency and supplementation on adiposity and metabolism in animal models	577
8. Effect of the vitamin D pathway on inflammation in adipocytes and adipose tissue	579
9. Conclusions	580
10. Summary points	581
References	581

## 29. Vitamin D and skeletal muscle

CHRISTIAN M. GIRGIS

1. Introduction	587
2. Skeletal muscle physiology	587
3. Vitamin D receptor in muscle	589
4. Vitamin D and calcium signaling in muscle	592
5. Vitamin D and phosphate signaling in muscle	593
6. Vitamin D uptake in skeletal muscle	594
7. Vitamin D, insulin signaling, and metabolism in muscle	594
8. Vitamin D, muscle contraction, and strength	595
9. Vitamin D, muscle development, and mass	597
10. Vitamin D, muscle injury, and repair	599
11. Vitamin D and age-related changes in muscle	600
12. Vitamin D and bone muscle crosstalk	601
13. Conclusions	601
14. Summary points	602
References	603
Further reading	607

## 30. Understanding vitamin D from mouse knockout models

DAVID GOLTZMAN,  
ANDREW C. KARAPALIS, RICHARD KREMER, AND  
DENGSHUN MIAO

1. Introduction	609
2. Vitamin D metabolism	609

3. Mineral and skeletal homeostasis	612
4. Calcium transport in intestine and kidney	612
5. Intestinal calcium absorption	613
6. Renal calcium reabsorption	613
7. Intestinal phosphate transport	613
8. Regulation of parathyroid gland function	614
9. Interaction of PTH and 1,25(OH) <sub>2</sub> D on calcium and phosphate homeostasis	614
10. Regulation of FGF23 production	615
11. Anabolic effects of vitamin D on the skeleton: role of VDR and 1 $\alpha$ -OHase in chondrocytes	615
12. Effects on skeletal mineralization	616
13. Effects on bone turnover	616
14. Effects on bone resorption	617
15. Effects on skeletal aging	617
16. Calcitriol and teeth	618
17. Extraskeletal actions of 1,25(OH) <sub>2</sub> D	619
18. Ectopic calcification	619
19. Cancer	619
20. Skin and hair follicles	621
21. Epidermal differentiation and the immune system	622
22. Conclusion	625
23. Summary points	625
References	625
Further reading	632

## 31. Pharmacology and pharmacokinetics of vitamin D

INEZ SCHOENMAKERS AND KERRY S. JONES

1. Overview	633
2. Vitamin D absorption	634
3. Kinetics of cutaneous synthesis	637
4. Tissue distribution	638
5. Metabolism and determinants of metabolic fate of vitamin D	640
6. Half-lives of vitamin D metabolites	642
7. Factors influencing half-life of vitamin D metabolites	644
8. The pharmacokinetics of bound and free vitamin D metabolites	647
9. Influence of DBP genotype and concentration on vitamin D metabolism and 25(OH)D half-life	649
10. Dose-response to vitamin D supplementation	650
11. The 3-epimer of 25(OH)D and 1,25(OH) <sub>2</sub> D	655
12. Catabolism and excretion	656
13. Vitamin D toxicity	656
14. Summary points	658
Acknowledgments	658
References	658

### 32. Vitamin D as a modifier of genomic function and phenotypic expression during pregnancy

CAROL L. WAGNER AND BRUCE W. HOLLIS

1. Introduction	669
2. Defining a “normal” circulating 25(OH)D concentration in humans	670
3. Unique vitamin D metabolism during pregnancy	671
4. Placental transfer of vitamin D to the fetus and its function	671
5. Vitamin D deficiency during pregnancy: Animal models and human studies	671
6. Vitamin D deficiency during pregnancy: Human studies	675
7. Conclusions	686
8. Summary points	686
References	686
Further reading	692

### 33. The role of vitamin D physiology in regulating calcium and bone metabolism in mother and child: pregnancy, lactation, postweaning, fetus, and neonate

BRITTANY A. RYAN AND CHRISTOPHER S. KOVACS

1. Introduction	693
2. Pregnancy	694
3. Lactation and postweaning recovery	705
4. The fetus	716
5. Neonate and infant	731
6. Conclusion	740
7. Summary points	742
References	742

### 34. Vitamin D and the placenta

JANE K. CLEAL, ROHAN M. LEWIS, AND NICHOLAS C. HARVEY

1. Introduction	761
2. The human placenta	762
3. Vitamin D, pregnancy, and the human placenta	765
4. Vitamin D effects on the placenta	769
5. Vitamin D, the placenta, and lifelong health	771
6. Conclusion	773
7. Summary points	773
References	773

### 35. Consequences of perinatal vitamin D deficiency on later bone health

REBECCA J. MOON, ELIZABETH M. CURTIS, JANE K. CLEAL, ELAINE M. DENNISON, CYRUS COOPER, AND NICHOLAS C. HARVEY

1. Introduction	777
2. Vitamin D physiology and epidemiology in pregnancy	777
3. The lifecourse determinants of osteoporosis	778
4. <i>In utero</i> vitamin D deficiency and bone health	784
5. Conclusion	792
6. Summary points	793
Acknowledgments	793
References	793
Further reading	799

### 36. Adolescence and acquisition of peak bone mass

KEVIN D. CASHMAN, RICHARD LEWIS, AND CONNIE M. WEAVER

1. Introduction	801
2. Pubertal bone acquisition	802
3. Serum 25(OH)D in children and adolescents	806
4. Vitamin D and intermediate endpoints of vitamin D and bone metabolism	811
5. Vitamin D and other predictors of calcium retention	815
6. Vitamin D and bone	815
7. Vitamin D and muscle	821
8. Vitamin D requirements in children and adolescents	821
9. Conclusions	823
10. Summary points	823
References	824

### 37. The role of vitamin D in orthopedic surgery

AASIS UNNANUNTANA, KATHERINE HASELTINE, TEERAPAT TUTAWORN, ALEKSEY DVORZHINSKIY, AND JOSEPH M. LANE

1. Introduction	831
2. Impact on orthopedic trauma	832
3. Impact on pediatric orthopedics	837
4. Impact on total joint arthroplasty	840
5. Conclusions	844
6. Summary points	845
References	845
Further reading	853

38. Vitamin D and muscle performance in athletes and older adults		13. Concluding remarks and future perspectives	917
LISA CEGLIA		14. Summary points	918
1. Introduction	855	References	918
2. Vitamin D—deficient myopathy	856		
3. Vitamin D and athletic performance	856	41. Vitamin D and the renin—angiotensin system	
4. Vitamin D and muscle strength and performance in older adults	860	YAN CHUN LI	
5. Conclusion	867	1. Introduction	925
6. Summary points	867	2. Overview of the renin—angiotensin system	925
References	867	3. Vitamin D regulation of the renin—angiotensin system	930
Further reading	871	4. Vitamin D and the renin—angiotensin system in disease	934
		5. Conclusion	943
39. Role in reproductive biology and dysfunction in women		6. Summary points	943
LUBNA PAL AND HUGH S. TAYLOR		References	944
1. Introduction	873		
2. Relevance of vitamin D for female reproductive biology: experimental models	874	42. Vitamin D: presence and function in the eye	
3. Relevance of vitamin D for female reproductive biology: gynecological disorders	874	GRAHAM R. WALLACE, SAAEHA RAUZ, AND DHRUV PAREKH	
4. Relevance of vitamin D for human female reproductive biology: human data	875	1. Introduction	953
5. Relevance of vitamin D in female reproductive disorders	876	2. Vitamin D and the eye	954
6. Conclusions	883	3. Ocular infection	955
7. Summary points	883	4. Dry eye disease	955

## 44. Vitamin D and the lung

KAREN MAES, GHISLAINE GAYAN-RAMIREZ, AND WIM JANSSENS

1. Introduction	997
2. Vitamin D in early life	998
3. Role of vitamin D in the defense against respiratory infections	1000
4. Vitamin D and lung infections	1004
5. COVID-19	1006
6. Conclusion	1007
7. Summary points	1007
References	1007

## 45. Design and synthesis of vitamin D analogs

MIGUEL A. MAESTRO

1. Introduction	1013
2. Synthetic approaches to vitamin D trienic system	1013
3. 19-Nor/21- <i>epi</i> /C-2 substituted analogs of 1,25(OH) <sub>2</sub> D <sub>3</sub>	1014
4. Side chain analogs of 1,25(OH) <sub>2</sub> D <sub>3</sub>	1017
5. A-ring analogs of 1,25(OH) <sub>2</sub> D <sub>3</sub>	1019
6. CD-ring modified analogs of 1,25(OH) <sub>2</sub> D <sub>3</sub>	1020
7. Fluorinated analogs of 1,25(OH) <sub>2</sub> D <sub>3</sub>	1021
8. 14- <i>epi</i> analogs of 1,25(OH) <sub>2</sub> D <sub>3</sub>	1022
9. Non-steroidal compounds	1022
10. Miscellaneous	1022
11. Advances in synthetic methodologies	1024
12. Conclusion	1024
13. Summary points	1025
References	1025

## 46. Structure function relationships of VDR ligands

HIROYUKI KOJIMA AND KEIKO YAMAMOTO

1. Introduction	1027
2. Agonist-bound structures of the VDR-LBD	1030
3. Apo structure of the VDR-LBD	1038
4. Antagonist-bound structures of the VDR-LBD	1040
5. Partial agonist-bound structures of the VDR-LBD	1046
6. Conclusions and perspectives	1047
7. Summary points	1047
References	1047
Further reading	1051

## 47. Modulating vitamin D receptor—coregulator binding with small molecules

DANIEL A. WEBB, MAIJA B. LEE, AND LEGGY A. ARNOLD

1. Introduction	1053
2. VDR coactivators	1054
3. VDR corepressors	1054
4. Peptide-based inhibitors of VDR—coregulator interactions	1055
5. Small molecule—based inhibitors of VDR—coregulator interactions	1056
6. Conclusion	1058
7. Summary points	1058
References	1058
Further reading	1061

## 48. Mass spectrometry assays of vitamin D metabolites

MARTIN KAUFMANN, LUSIA SEPIASHVILI, AND RAVINDER J. SINGH

1. Introduction	1063
2. Approaches and utility of vitamin D metabolite measurements in the clinical laboratory setting	1064
3. Overview of methodology for analysis of circulating vitamin D	1069
4. Application of LC—MS/MS to the study of vitamin D metabolism in animal models	1074
5. Conclusions	1079
6. Summary points	1080
References	1080

## 49. Measurement and quality assessment of total and free 25-hydroxyvitamin D

CHRISTOPHER T. SEMPOS, EMMA L. WILLIAMS, DIANE C. KRUEGER, NEIL C. BINKLEY, AND RENE F. CHUN

1. Introduction section 1: 25-hydroxyvitamin D assay standardization	1085
2. Vitamin D standardization program (VDSP) objectives	1086
3. Introduction to performance testing (PT)/external quality assessment schemes (EQA)	1093
4. Prospective standardization	1094
5. Protocol for retrospective standardization	1096
6. Performance testing/quality assessment of assays for vitamin D metabolites	1099
7. Beyond standardization	1101
8. Vitamin D standardization program efforts—into the future	1101

<b>xiv</b>	Contents	
9. Summary and conclusions	1104	3. Mass spectrometry imaging 1116
10. Section 2: Free and bioavailable 25-hydroxyvitamin D	1104	4. Mass spectrometry imaging methods for spatial distribution of vitamin D metabolites in tissues 1122
11. Summary points	1108	5. Future MSI platforms and technological developments 1125
References	1109	6. Conclusion 1126
50 Vitamin D tissue distribution by mass spectrometry imaging		7. Summary points 1126
DIEGO F. COBICE AND KARL W. SMITH		References 1126
1. Introduction	1115	Further reading 1129
2. Vitamin D	1115	<b>Index for Volume 1 1131</b>

## VOLUME II

### 51. Defining thresholds for vitamin D I: scientific rationale for serum 25-hydroxyvitamin D cutoffs of 25 and 50 nmol/L

ANDREA L. DARLING AND SUSAN A. LANHAM-NEW

1. Introduction 1
2. Justification for serum 25(OH)D concentration >25 nmol/L 1
3. Justification for serum 25(OH)D concentration >50 nmol/L 3
4. Issues with reaching 25(OH)D thresholds for specific groups 5
5. Other issues surrounding definition of thresholds for vitamin D 7
6. Conclusion 7
7. Summary points 7
- References 7

### 52. Defining thresholds for vitamin D II

REINHOLD VIETH

1. Introduction 11
2. Human biology 14
3. Nutrition clinical trials cannot match the quality of evidence achieved with drugs 15
4. Cancer 17
5. Mortality 19
6. Cardiovascular 20
7. Toxicity 21
8. Multiple sclerosis 21
9. COVID-19 22
10. Conclusion 26
11. Summary points 26
- References 26

### 53. Methods of evaluating population studies of vitamin D: strengths and weaknesses

EDWARD GIOVANNUCCI

1. Introduction 31
2. Methods of assessing vitamin D status 32
3. Main challenges in the epidemiologic study of vitamin D and disease 36
4. Summary of study designs of vitamin D 38
5. Conclusions 43
6. Summary points 44
- References 44
- Further reading 46

### 54. Worldwide vitamin D status

NATASJA VAN SCHOOR, RENATE DE JONGH, AND PAUL LIPS

1. Introduction 47
2. Assessment of vitamin D status 48
3. Study selection 49
4. Multicenter and global studies using a central laboratory facility 66
5. Ethnicity/migration 66
6. Nutrition 66
7. Risk groups 66
8. Trends in vitamin D status 69
9. Implications 69
10. Conclusions 70
11. Summary points 70
- References 70

### 55. Vitamin D in food—Compounds, stability, sources

JETTE JAKOBSEN AND MARIE BAGGE JENSEN

1. Introduction 77
2. Chemical structure of vitamin D vitamers 78
3. Stability of vitamin D 78
4. Analytical methodology 81
5. Vitamin D in food 82
6. Conclusion 92
7. Summary points 92
- References 92
- Further reading 96

### 56. Determinants of vitamin D levels from sun exposure: a global perspective

WILLIAM B. GRANT, HARJIT P. BHATTOA, AND PAWEŁ PLUDOWSKI

1. Introduction 97
2. Vitamin D production from solar UVB exposure 97
3. Factors affecting 25-hydroxyvitamin D concentrations 98
4. Endogenous characteristics 101
5. Behavioral determinants 102
6. Predicting vitamin D deficiency 107
7. Nonvitamin D benefits from solar UV exposure 107
8. Conclusion 108
9. Summary points 108
- References 108

### 57. Vitamin D supplement use as a public health strategy to augment diet and sustain population adequacy

SUSAN J. WHITING AND MONA S. CALVO

1. Introduction 115

2. Thresholds for 25(OH)D	117	5. Variants with evidence for replicated association with 25(OH)D	187
3. Country-level guidelines for supplements use	118	6. Gene—environment interaction	192
4. Supplement use improves vitamin D status: Canada as a case study	120	7. Applications and practical implications	193
5. Characteristics of vitamin D supplement users	123	8. Conclusions	194
6. Considerations when choosing to take a vitamin D supplement	124	9. Summary points	194
7. Safety of vitamin D supplements	127	References	195
8. Guidance is needed for use of vitamin D supplements	129	61. Effect of vitamin D on health and disease: evidence from Mendelian randomization	
9. Conclusion	131	KATERINA TRAJANOSKA, FERNANDO RIVADENEIRA, J. BRENT RICHARDS, AND DESPOINA MANOUSAKI	
10. Summary points	131	1. Introduction	201
References	131	2. Type 2 diabetes	213
58. Vitamin D and food fortification		3. Risk of cancers	214
KEVIN D. CASHMAN AND MAIREAD KIELY		4. Risk of cardiovascular events	214
1. Introduction	135	5. Hypertension	215
2. Current intakes of vitamin D in young and adult populations in North America and Europe and how these compare against dietary targets	138	6. Musculoskeletal outcomes	215
3. Dietary strategies for increasing vitamin D intake: bridging the gap by food fortification	143	7. Lung function and respiratory conditions	216
4. Consideration of other vitamin D—fortified foods	148	8. Immune disorders	216
5. Vitamin D—biofortified foods	150	9. Pregnancy-related outcomes	217
6. Safety considerations and prerequisite data required prior to initiating public health measures	154	10. Neuropsychiatric outcomes	217
7. Conclusions	155	11. COVID-19	217
8. Summary points	156	12. Mortality risk and aging	217
References	156	13. Other outcomes	218
Further reading	160	14. Nonlinear MR studies	218
59. Bariatric surgery, vitamin D, and bone loss		15. Conclusion	219
TIFFANY Y. KIM AND ANNE L. SCHAFER		16. Summary points	219
1. Introduction	161	References	219
2. Skeletal effects of bariatric surgery	163	Further reading	222
3. Potential mechanisms of bone loss	166	62. Growth plate histology, bone histomorphometry, and radiologic features of nutritional rickets and osteomalacia	
4. Prevention and treatment of skeletal effects	175	SUMA UDAY AND WOLFGANG HÖGLER	
5. Summary points	177	1. Introduction	223
Acknowledgments	177	2. Terminology related to bone formation and mineralization	224
References	177	3. The growth plate	224
60. Genetic determinants of 25-hydroxyvitamin D concentrations		4. Mineralization	226
ELINA HYPPÖNEN, ANG ZHOU, AND KARANI S. VIMALESWARAN		5. Bone histomorphometry in osteomalacia	227
1. Introduction	185	6. Bone mineral density distribution in osteomalacia	228
2. 25(OH)D synthesis and metabolism	185	7. Radiological features of rickets and osteomalacia	229
3. Heritability of serum 25(OH)D levels	186	8. Radiographic differences between various forms of rickets	231
4. Genome-wide association studies of 25(OH)D	186	9. Imaging choice in rickets and osteomalacia	236
		10. Conclusion	237

11. Summary points	238	8. Hyperphosphatemia-mediated hypocalcemia	314
References	238	9. Hypocalcemia due to accelerated skeletal mineralization	315

Further reading	510

## 76. The role of vitamin D in type 2 diabetes

ANASTASSIOS G. PITTAS

1. Introduction	511
2. Epidemiology and burden of type 2 diabetes	511
3. Biologic plausibility of the link between vitamin D and type 2 diabetes	512
4. Observational studies on vitamin D and type 2 diabetes	515
5. Vitamin D supplementation in people with normal glucose tolerance or type 2 diabetes	526

6. Vitamin D for prevention of type 2 diabetes in people with prediabetes	533
7. Optimizing blood 25(OH)D levels and the concept of “treat-to-target”	543
8. Effect modification of vitamin D supplementation by BMI	545
9. Safety of vitamin D supplementation for prevention of type 2 diabetes	546
10. Conclusions	546
11. Summary points	547
References	547

## 77. Liver metabolism and disease

BINGNING DONG

1. Introduction	559
2. Vitamin D/VDR signaling and antiinflammatory responses in the liver	561
3. Vitamin D/VDR signaling in liver fibrosis and NASH	562
4. Conclusions	563
5. Summary points	563
References	563

## 78. Vitamin D, hypertension, and cardiovascular disease

ARMIN ZITTERMANN AND STEFAN PILZ

1. Introduction	567
2. Vitamin D metabolism and regulation with special reference to cardiovascular disease	568
3. Vitamin D effects on cardiovascular cells	569
4. Vitamin D effects in experimental animals	569
5. Rickets, osteomalacia, and cardiovascular disease	570
6. Vitamin D status and cardiovascular outcomes in observational studies	570
7. Genetic studies on vitamin D and cardiovascular outcomes	571
8. Vitamin D supplementation studies	574
9. Cardiovascular events in large vitamin D supplementation trials in general populations	577
10. Vitamin D in end-stage organ failure	578
11. Adverse vitamin D effects on the cardiovascular system	579
12. Conclusion	580
13. Summary points	580
References	581
Further reading	586

## 79. Vitamin D and renal disease

ADRIANA DUSSO, KEVIN T. BAUERLE, RONG MEI ZHANG,  
AND CARLOS BERNAL-MIZRACHI

1. Introduction	587
-----------------	-----

2. Renal regulation of the vitamin D endocrine system	588	7. Summary points	641
3. Alterations in vitamin D bioactivation to 25(OH)D in chronic kidney disease	589	References	642
4. Alterations in renal 1,25(OH) <sub>2</sub> D synthesis and 25(OH)D and 1,25(OH) <sub>2</sub> D catabolism in chronic kidney disease	592	Further reading	649
5. Alterations in 1,25(OH) <sub>2</sub> D production by extrarenal 1 $\alpha$ -Hydroxylases in chronic kidney disease	594		
6. Alterations in 1,25(OH) <sub>2</sub> D/VDR endocrine and autocrine/paracrine actions in CKD	596	<b>82. Vitamin D and Paget's disease</b>	
7. Vitamin D control of secondary hyperparathyroidism	599	NORIYOSHI KURIHARA AND G. DAVID ROODMAN	
8. Vitamin D control of skeletal health in CKD unrelated to the attenuation of secondary hyperparathyroidism	602	1. Introduction	651
9. Vitamin D maintenance of renal FGF23/klotho axis: relevance for renal and cardiovascular protection	603	2. Mechanism of action of 1,25(OH) <sub>2</sub> D <sub>3</sub> on osteoclast formation	652
10. Vitamin D control of hypertension and systemic inflammation conferring renal and cardiovascular protection independently of renal or systemic klotho levels	606	3. Increased levels of TAF12 in osteoclast precursors from Paget's disease patients contribute to their hyperresponsivity to 1,25(OH) <sub>2</sub> D <sub>3</sub>	652
11. Progress to improve current recommendations for the evaluation of vitamin D status and for the design of safe and effective vitamin D interventions	609	4. Mechanism of action of TAF12 in the increased 1,25(OH) <sub>2</sub> D <sub>3</sub> responsivity of OCL precursors from Paget's patients	655
12. Summary points	610	5. Marrow stromal cells derived from P62 <sup>P394L</sup> knock-in mice and P62 <sup>P392L</sup> Paget's patients are hyperresponsive to 1,25(OH) <sub>2</sub> D <sub>3</sub> and display enhanced RANKL production in response to 1,25(OH) <sub>2</sub> D <sub>3</sub>	657
References	611	6. Deleting TAF12 in mouse OCLs inhibits bone destruction and bone-remodeling	657
		7. Serum concentration of 1,25(OH) <sub>2</sub> D <sub>3</sub> in Paget's patients	659
<b>80. Vitamin D and kidney stones</b>		8. Conclusions	660

## 85. Vitamin D status and cancer incidence, mortality, and prognosis

HANSEUL KIM, IRENE SHUI, AND  
EDWARD GIOVANNUCCI

1. Introduction	719
2. Cancer incidence	720
3. Cancer mortality and survival	724
4. Genetic variation and gene expression in the vitamin D pathway	730
5. Conclusions	732
6. Summary points	733
References	733

## 86. Antiproliferative and immunoregulatory actions of vitamin D derivatives on hematological malignancies: control of differentiation, proliferation, and cell death

GEORGE P. STUDZINSKI, ELZBIETA GOCEK, EWA  
MARCINKOWSKA, AND MICHAEL DANILENKO

1. Differentiation of myeloid leukemia cells by vitamin D derivatives	741
2. Signaling and execution of monocytic differentiation induced by VDDs	742
3. Transcription factors in VDD-induced differentiation	752
4. Effects of VDDs on the cell cycle and proliferation of human leukemia cells	755
5. Effects of VDDs on cell survival and cell death	764
6. Effects of VDDs on lymphoid lineage cells and immunity	765
7. Clinical applications of VDD actions against hematopoietic malignancies	768
8. Significance of basic and clinical studies of VDDs in hematopoietic malignancies: from bench to bedside	774
9. Conclusions	775
10. Summary points	775
References	776
Further reading	795

## 87. Vitamin D, inflammation, and cancer

ENIKÖ KALLAY, MARTIN SCHEPELMANN, AND LAURA  
BUBURUZAN

1. Introduction	797
2. Vitamin D and the vitamin D system	798
3. Inflammation	798
4. Inflammation-associated cancer	803
5. Conclusions	813
6. Summary points	814
References	814
Further reading	824

## 88. Vitamin D actions in mammary gland and breast cancer

JOELLEN WELSH AND MIN JI BAK

1. Introduction	825
2. Observational and interventional studies on vitamin D and breast cancer	827
3. Expression and function of the vitamin D pathway in normal and neoplastic breast cells/tissues	832
4. Impact of vitamin D signaling in animal models of breast cancer	839
5. Genomic profiling of VDR agonists in breast cancer model systems	841
6. Mechanistic insight into vitamin D actions in breast cancer	844
7. Conclusion	849
8. Summary points	850
References	850

## 89. Vitamin D and colorectal cancer

GEMMA FERRER-MAYORGA, ALBERTO MUÑOZ, AND  
JOSÉ MANUEL GONZÁLEZ-SANCHO

1. Introduction	859
2. Human observational and intervention studies	863
3. Expression of vitamin D hydroxylases and the vitamin D receptor in colorectal cancer	864
4. Mechanism of action of 1,25(OH) <sub>2</sub> D <sub>3</sub> in colorectal cancer	868
5. Animal models	881
6. Conclusion	885
7. Summary points	886
References	886

## 90. Vitamin D in the management of lung cancer: influence of tumor stage, tumor genotype, and treatment modality

TATIANA SHAUROVA, HANNAH CALKINS, MUKUND  
SESHADRI, CANDACE S. JOHNSON, AND  
PAMELA A. HERSHBERGER

1. Introduction	901
2. Vitamin D may have tumor cell intrinsic and tumor cell extrinsic activities in lung cancer	903
3. The role of vitamin D in the chemoprevention of non-small-cell lung cancer	904
4. The role of vitamin D in management of early-stage lung cancer	905
5. The role of vitamin D in the management of advanced lung cancer	905
6. Strategies to maximize vitamin D signaling in lung cancer	909
7. Conclusions	910
8. Summary points	910

Acknowledgments	911	<b>94. Vitamin D and antibacterial immunity</b>

1. Introduction	967	9. Antiviral CD4 T cell immunity and 1,25(OH) <sub>2</sub> D	1019
2. UV-induced DNA damage, repair, and immune suppression	968	10. Antiviral CD8 T cell immunity and 1,25(OH) <sub>2</sub> D	1021
3. The vitamin D system and skin cancers	972	11. B cell responses to viruses and 1,25(OH) <sub>2</sub> D	1021
4. Mechanisms of protection from UV-induced skin tumors	975	12. Conclusions	1022
5. Conclusions	983	13. Summary points	1022
6. Summary points	984	References	1023
References	985	Further reading	1034
Further reading	993		

## 96. Vitamin D and adaptive immunity in health and disease

DREW A. GLENCROSS, CHARLOTTE CHEADLE, AND CATHERINE M. HAWRYLOWICZ

1. Introduction	1035
2. Epidemiological and other evidence supporting a role of vitamin D in immune disease	1036
3. Translational studies as a window to study effects of vitamin D on adaptive immunology	1036
4. Actions of vitamin D on proinflammatory T lymphocyte responses	1037
5. Naïve T cells	1037
6. Effects of vitamin D on CD4+ T cell subsets	1038
7. $\gamma\delta$ T cells	1040
8. CD8+ T cells	1041
9. Actions of vitamin D on regulatory T lymphocyte responses	1041
10. Actions of vitamin D on B lymphocytes	1043
11. Actions of vitamin D on the immune microenvironment and the function of APCs	1043
12. Effects of vitamin D upon immunometabolism in APC and T cells	1044
13. Translational aspects of vitamin D regulation of adaptive immunity—vitamin D and vaccine responses	1045
14. Disparity between association, translational, and clinical studies	1045
15. Protection from exacerbation of airway disease by vitamin D	1048
16. UVB and vitamin D at the skin—how does this compare with oral supplementation	1048
17. Conclusions	1049
18. Summary points	1050
References	1051

## 97. Vitamin D, microbiota, and inflammatory bowel disease

MARGHERITA T. CANTORNA AND JUHI ARORA

1. Introduction	1057
2. What is inflammatory bowel disease?	1057
3. Who gets inflammatory bowel disease?	1058
4. The immune system and inflammatory bowel disease	1062
5. Experimental models of inflammatory bowel disease	1065
6. Current treatments for inflammatory bowel disease	1067
7. Vitamin D as a treatment option for inflammatory bowel disease	1068
8. Conclusions	1069
9. Summary points	1069
References	1069

## 98. Vitamin D and tuberculosis

ADRIAN R. MARTINEAU

1. Introduction	1075
2. The immune response in tuberculosis	1076
3. Influence of vitamin D on the immune response to MTB	1076
4. Historical studies	1079
5. Studies with MTB infection as an end point	1081
6. Studies with active TB disease as end point	1082
7. Studies of treatment outcome	1083
8. Conclusions	1084
9. Summary points	1085
References	1085

## 99. The role of vitamin D in COVID-19

SEBASTIAN T. LUGG AND DAVID R. THICKETT

1. Introduction	1091
2. Vitamin D and immunity and inflammation: relevance to COVID-19 infection	1091
3. Vitamin D and respiratory tract infections	1094
4. Vitamin D and COVID-19: geographical latitude and UV radiation	1094
5. Vitamin D and COVID-19: community observational studies	1095
6. Vitamin D and COVID-19: hospital observational studies	1099
7. Vitamin D and COVID-19: effects of polymorphisms in VDR and vitamin D-binding protein genes	1100
8. Vitamin D and SARS-CoV-2 vaccination response	1100
9. Vitamin D supplementation and COVID-19	1100
10. Current guidance of COVID-19 and vitamin D and future research	1104
11. Conclusions	1104
12. Summary points	1105
References	1105
Further reading	1108

## 100. Vitamin D and type 1 diabetes

PIETER-JAN MARTENS, CONNY GYSEMANS, AND CHANTAL MATHIEU

1. Introduction	1109
2. Effect of vitamin D deficiency on type 1 diabetes presentation	1110
3. Relation between vitamin D-related genes and the genetic predisposition to type 1 diabetes	1110
4. Vitamin D and the beta cell	1111
5. Vitamin D as an immune modulator in type 1 diabetes	1113

6. Interventions using vitamin D to prevent or arrest type 1 diabetes	1113	4. Vitamin D deficiency and RA disease risk, severity, and progression	1190
7. Immune effects of interventions with vitamin D in type 1 diabetes	1116	5. Genetic variation in the vitamin D system and RA	1199
8. Vitamin D analogs and type 1 diabetes	1118	6. Effects of supplementary vitamin D on RA	1200
9. Vitamin D in combination therapy to prevent or arrest type 1 diabetes	1119	7. Conclusions	1201
10. Conclusion	1122	8. Summary points	1201
11. Summary points	1122	References	1201
References	1122	Further reading	1206
 101. Vitamin D mechanisms of protection in multiple sclerosis		 104. Psoriasis and other skin disorders	
COLLEEN E. HAYES, ANNE L. ASTIER, AND MATTHEW R. LINCOLN		JÖRG REICHRATH AND MICHAEL F. HOLICK	
1. Introduction	1130	1. Introduction/historical overview	1207
2. Vitamin D and MS genetics	1131	2. Pathogenesis of psoriasis	1208
3. MS sexual dimorphism	1134	3. The vitamin D system in normal and psoriatic skin	1208
4. CD4 <sup>+</sup> FOXP3 <sup>+</sup> T regulatory cells and hormonal regulation of FOXP3	1137	4. Physiological and pharmacological actions of vitamin D analogs in normal and psoriatic skin	1211
5. Interplay between vitamin D and CD4 <sup>+</sup> type 1 regulatory T cells in MS	1145	5. Clinical use of 1,25(OH) <sub>2</sub> D <sub>3</sub> and its analogs in psoriasis and other skin diseases	1214
6. Oligodendrocytes, DNA methylation, and the methionine cycle	1149	6. Vitamin D in prevention and therapy of other skin diseases	1218
7. Some reflections on vitamin D <sub>3</sub> supplementation trials in MS	1155	7. Evaluation of new vitamin D analogs, with less calcemic activity, which can be used for the treatment of hyperproliferative skin disorders	1223
8. Conclusion	1156	8. Conclusion	1224
9. Summary points	1158	9. Summary points	1224
References	1159	References	1225
 102. Vitamin D and the epidemiology of multiple sclerosis		Further reading	1230
KASSANDRA L. MUNGER AND ALBERTO ASCHERIO		 105. Vitamin D, acute respiratory infection, and Asthma/COPD

# In memoriam

---

**Anthony W. Norman, Ph.D. (1938–2019) and  
Helen L. Henry, Ph.D. (1944–2018)**

Anthony (Tony) Norman passed away about a year after the death of his partner in life and science, Helen Henry. Tony was born in Ames, Iowa in 1938 and he grew up in Ann Arbor, Michigan, where his father was a Professor and later on Vice President for Research at the University of Michigan. Tony received his BA degree from Oberlin College in 1959, and then pursued Ph.D. training in Madison, Wisconsin, in the laboratory of Hector F. DeLuca (the laboratory originally founded by Harry Steenbock). Tony was actually the first of a long series of Ph.D. students of Hector. The title of his 1963 Ph.D. thesis was "The preparation, distribution and metabolism of  $^3\text{H}$ -vitamins D<sub>2</sub> and D<sub>3</sub>." He then did his postdoctoral research in 1963–64, in the laboratory of the Nobel Laureate Paul D. Boyer at the University of California, Los Angeles, on the topic of electron transport and oxidative phosphorylation. During this postdoctoral period, Tony started his own research projects at the University of California, Riverside, where he spent his entire academic career. There, his first graduate student was Mark Haussler, who would become another giant in the vitamin D field! The next few years would lead to the discovery that would lead to the discovery that production of the active vitamin D metabolite required mRNA/protein synthesis and that the unknown metabolite

accumulated in the nucleus. Soon thereafter, the active metabolite was identified as  $1,25(\text{OH})_2\text{D}$  in Hector's laboratory as well as in Tony's laboratory and in Egon Kodicek's laboratory (Cambridge, UK). This resulted in a major conceptual milestone: "vitamin D is metabolized into a ligand for a nuclear receptor, VDR, its synthesis is feedback controlled as a hormone and it works as a hormone."

Tony was an innovative and productive scientist and author, as demonstrated by more than 700 peer reviewed publications and an H-index of 98 (2012). His major research topics spanned basic biochemistry to clinical research, and dealt with many aspects of vitamin D metabolism and actions. These topics included calcium-binding proteins, intestinal calcium transport, and the action of vitamin on the immune system. Clinically related publications dealt with the consequences of vitamin D deficiency on glucose metabolism and the therapeutic effects of  $1,25(\text{OH})_2\text{D}$  in patients with chronic renal failure (with J. Coburn). He also had a long-standing fruitful collaboration with Bill Okamura regarding the structure function relationship of vitamin D analogs. Later in his career, he pioneered work on nongenomic or rapid actions of the vitamin D metabolites and analogs.

Tony was not only an original hard-working scientist, but in line with his family history, he was also an avid teacher. His commitment to education was evident not only through his teaching at UC Riverside but also through his role as an author or editor of books on endocrinology (frequently together with Helen Henry) and above all by organizing the serial Vitamin D Workshops. He started this initiative as a small-scale meeting in Frankfurt (Germany) in 1973, followed by a somewhat bigger meeting in Wiesbaden (Germany) and thereafter by holding a meeting every 3 years, alternatively in North America and Europe. These meetings were very well attended (up to more than 600 persons for the 1991 Paris workshop), especially so because the topics included all aspects of vitamin D, from chemistry, basic biochemistry and physiology, to animal research and clinical practice. The focus shifted over time in line with new scientific data and clinical practice. For example, the first meetings paid much

attention to the consequences of chronic renal failure on bone health, whereas at later times, dermatology, cancer, immunology, and osteoporosis were more on the forefront. He also introduced a rule to promote the publication of the proceedings of the meetings, initially in a handbook and later on as a special issue of *The Journal of Steroid Biochemistry and Molecular Biology*, so as to reach out to a larger audience. After the Brugge Meeting in 2009, Tony and his long term coorganizer Roger Bouillon decided to alter the organization of the workshop to allow a rotating group of vitamin D experts the opportunity of developing and managing the workshops every year. Thereby, his legacy of bringing together the vitamin D research community was assured for the future.

Rising to Distinguished Professor of Biochemistry, Tony also played important roles at UC Riverside as Department Chair, Divisional Dean and Program Director, and Chair of the Academic Senate.

Helen Henry was born in 1944 and grew up in Tulsa, Oklahoma. She completed her BSc in 1965 and Ph.D. in 1970 at Washington University in St. Louis. After her postdoctoral research at Ohio State University, she joined Tony's laboratory in Riverside (1974). In 1978, Helen began an independent academic career in the Department of Biochemistry at UC Riverside focused on vitamin D metabolism. Her laboratory made major contributions to the understanding of vitamin D metabolism, particularly regulation of the production of the active vitamin D hormone by the kidney. She pioneered the use of cell culture systems to study renal vitamin D metabolism. With over 80 publications, many of which were coauthored with Tony (and vice versa), Helen had a long and productive career.

Like Tony, Helen had a great passion for teaching and together they developed several courses on nutrition, endocrinology, and introductory biochemistry, which they taught together with other UC Riverside faculty for over 30 years. Even after her retirement in 2008, Helen remained active in teaching and administration at UC Riverside. Both Tony and Helen were also members of the editorial board of several journals, and they jointly edited several editions of the textbook *Hormones*. Evidently, Tony and Helen contributed at least one chapter in each of the editions of Elsevier's *Vitamin D* "bible."

Moreover, Helen and Tony were a team not only in the laboratory but also at home. They were devoted to family and facilitated meetings of their whole family from time to time, often at their "Sea Ranch" in Northern California. Sadly, Helen Henry died, after a long and courageous battle against disease, in May 2018. Tony Norman passed away in June 2019. Tony and Helen are survived by their children Thea, Jacqueline, and Derek and nine grandchildren. There is no doubt

that Tony and Helen left a lasting heritage and will remain remembered and respected by the vitamin D research community.

**Ronald L. Horst, Ph.D. (1949–2019)**

The field of vitamin D and calcium metabolism lost a beloved colleague on May 23, 2019, when Dr. Ronald L. Horst at the age of 69 passed following a 15-year battle with prostate cancer. He was diagnosed in December of 2004 and was given only about 2 years to survive, but Ron would not accept that diagnosis and fought it for more than a decade and a half. Much of that fight involved the use of large oral doses of vitamin D. When he was first diagnosed back in 2004, ironically, he was quite vitamin D deficient and he quickly corrected that by taking 8000 IU/day of vitamin D. Many of his academic colleagues were horrified by this and warned him of the impending renal damage if he continued and of course Ron ignored them and increased his intake as time went on to 30,000 IU/day. Ron also received traditional therapy for his cancer while taking the vitamin D and his doctors at the Mayo Clinic were constantly amazed by the lack of progression of his cancer. He would tell them that it was the vitamin D providing the protection to which they would respond, we don't think so but keep doing it. It was a gallant fight, but since nobody is ever cured of metastatic prostate cancer, Ron finally succumbed in 2019.

Ron grew up on a dairy farm in West Virginia where he learned the value of hard work that would continue to serve him for the rest of his life. Ron would often tell me that after milking the cows at 4 a.m. he would go to school to rest. Upon graduating from Hedgesville High School in 1967, he began his undergraduate degree at West Virginia University, where he majored of course in Dairy Science and played football for The Mountaineers for a year under Bobby Bowden. Following his graduation from WVU, he went on to the University of Wisconsin–Madison to pursue a Ph.D. in Biochemistry and Dairy Science. During his time in Madison, Ron became involved with the laboratory of Hector DeLuca where he became immersed in the metabolism and measurement of vitamin D and its metabolites. He subsequently applied these techniques to his studies on circulating  $1,25(\text{OH})_2\text{D}$  and bovine milk fever publishing a seminal article in the journal *Science* which was quite a feat for any student.

Ron left his postdoc position with Drs. DeLuca and Neil Jorgensen at UW to begin his career as a scientist at the National Animal Disease Center, USDA ARS in 1977. His mission was to work on metabolic mineral diseases of livestock. His main focus was on milk fever in dairy cows, a disease affecting about 7% of cows annually. To better understand calcium homeostasis in the cow, Ron established improved assays for vitamin D metabolites in blood and tissues. This led to breakthrough understanding of the metabolism of vitamin D compounds within the body. Ron was not satisfied only dealing with his role in agriculture, so he expanded his studies into human medicine through collaboration with too many individuals to list in this memorial. If you search out his PubMed bio, you will see just how extensive this list was. These studies with medical researchers throughout the world enhanced our understanding of renal failure, rickets, hyperparathyroidism, hypercalcemia of malignancy, the association of vitamin D insufficiency and increased risk of developing certain cancers, and osteoporosis. Ron found that vitamin D<sub>3</sub> and its metabolites were more biologically active than were their vitamin D<sub>2</sub> counterparts. His NADC group discovered VDR of bone and intestine declined with age. The discovery of VDR in thymus tissue opened the door to exploration of the role of vitamin D in immune competency. The NADC group Ron led for 29 years is known throughout the world for their work on bovine milk fever; they discovered that high dietary potassium induced a metabolic alkalosis in pregnant dairy cows which reduced the sensitivity of the tissues to PTH. Using this knowledge, Ron and his colleagues devised dietary treatments that decreased the incidence of milk fever in dairy cattle. Ron also elucidated the processes of activation and deactivation of vitamins A and D. The awards that Ron received for his research are truly

astounding and include the American Feed Manufacturing Association Award for Dairy Science, the UpJohn Physiology Award, the Agway Young Scientist Award, the Dean Food Award, the Presidential Meritorious Senior Professional Award, the ARS Scientific Hall of Fame Award, and the Spencer Award in Chemistry. Ron retired from the USDA in 2007 and he and I founded Heartland Assays that analyzes serum and food vitamin D content for commercial entities.

Above all else, Ron was a family man and the best friend a person could ever have. While in Wisconsin, he met the love of his life, Marina 'Myke' Fitzsimmons and they married in 1973. They were blessed with three daughters, Jamie, Emily, and Anna. Those daughters provided Ron with four grandsons who Ron spent as much time with as possible. Following Ron's retirement, he and I purchased homes in Victor, Idaho, where our families spent the summers together until his passing. I can't express the good times we had out there doing outdoor activities including fishing for trout on Henry's Lake. Doing that you could not find a happier man and I miss him every single day.

**Bruce W. Hollis**

*Medical University of South Carolina, Charleston*

#### **Graham Carter (1940–2022)**

On May 18, 2022, we lost Graham Carter, one of the foremost vitamin D analysts and the founder of DEQAS (Vitamin D External Quality Assessment Scheme). Graham established DEQAS in 1989 after a number of international studies brought attention to the poor performance of clinical assays for  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$ . As a Senior Biochemist working at London's

Charing Cross Hospital, Graham recognized that clinical services, commercially available kits, and research assays needed to perform at an acceptable standard and that establishing a scheme to prepare and distribute quarterly samples and then collect the results for external standardization would greatly benefit the vitamin D field. Vitamin D scientists soon embraced the idea and DEQAS had over 1200 participants globally in 2013. Graham's career started with an MSc in Clinical Biochemistry from the University of Surrey; and he was appointed Consultant Clinical Scientist in 1991 and later an Honorary Senior Research Fellow of Imperial College, London, in 2001. Graham continued at the helm of DEQAS uninterrupted from 1989 to 2018.

The DEQAS program has encouraged an improvement in performance by helping clinical chemists and kit manufacturers alike to quickly recognize problems and rectify them. Graham initiated an Advisory Panel in 1997 consisting of vitamin D analysts and steroid biochemists to help with specific problems involving the chemistry of vitamin D and issues connected with data management. Graham Carter carried out this liaison with all parties involved in D assays with considerable diplomacy, recognizing that gradual improvement in the assays was the main goal. Graham served DEQAS faithfully for close to 30 years and among his final achievements was to negotiate an agreement with NIST and later CDC-Atlanta to provide 25(OH)D target values for all samples circulated quarterly. He successfully passed on the reins of DEQAS to the current administrator, Dr. Emma Walker, in 2018 when he retired. Current DEQAS results provide values for the main circulating form 25(OH)D, the hormone 1,25(OH)<sub>2</sub>D, the chief catabolite, 24,25(OH)<sub>2</sub>D, and the neonatal metabolite, 3-epi-25(OH)D. Graham's legacy is the achievement of a truly global organization that has facilitated a big improvement in clinical vitamin D assays and accordingly, scientific publications in the vitamin D field. Graham Carter's death will leave a big void in the field of vitamin D analysis that will be hard to replace.

Graham enjoyed his time away from the laboratory with travel, most significantly to the Caribbean island of Grenada. Having been introduced to the island by his friend and colleague Vernon Scoon, he and his wife Brigitte bought a plot of land and went on to build a home where they lived for many years. When not abroad, his interests were much more local to home in England where he enjoyed ringing church bells at his local church, Ash-cum-Wrotham in Kent. He was also a lifelong musician, and as a child he was the head chorister at Truro Cathedral in Cornwall, where he learned the piano. After a long break, he returned to the piano later in life, ultimately achieving an ABRSM Grade 8 with distinction. He disliked performing to

others, but enjoyed attending concerts and learning and practicing Beethoven piano sonatas. During the pandemic, he found the confinement of lockdown hard, and took up piano lessons by Zoom, a habit he kept up even as his health started to decline with his last piano lesson only a few weeks before his death. Graham is survived by his wife Brigitte and his two sons, Richard and Tim.

*Glenville Jones with input from Hugh Makin, Elaine Gunter (all of DEQAS), and Graham's son Richard Carter*

#### Professor Judith Elizabeth Adams (1945–2017)

Professor Judith Elizabeth Adams, 'Judy' to her friends, was an eminent skeletal radiologist who passed away after a short illness on 30th September 2017. Judy was born 16th May 1945, in Liverpool and grew up in Northern Rhodesia (now Zambia). She trained at University College Hospital, London, UK, with her radiology career beginning in 1972. Her mentors included Sir Godfrey Hounsfield, the inventor of X-ray computed tomography, and Sir Charles Dent, a pioneer of metabolic bone disease and particularly vitamin D metabolism in the United Kingdom. She often reflected on her learnings from both pioneers and undoubtedly, Charles Dent, and latterly Professors Bill Stanbury and Barbara Mawer, enthused her with a passion for vitamin D research. She joined the University of Manchester in 1976 and became a Professor of Radiology and Head of Clinical Radiology in 1993. She served as the Dean, member of council, and Vice President of the Royal College of Radiologists. Judy was a member of many societies, including the

American Society for Bone and Mineral Research, the European Calcified Tissue Society, the Royal Osteoporosis Society and the Bone Research Society (UK), and also the International Skeletal Society and European Society for Skeletal Radiologists. She traveled the world attending the International Bone Densitometry Workshop's and hosting the 1987 Workshop in the United Kingdom.

Judy was a pioneer in the use of radiographic and bone densitometry in the diagnosis of osteoporosis and vertebral fracture recognition. She led and coauthored several national and international guidance documents for the clinical application of bone densitometry in pediatric and adult fields. She played a pivotal role in the collection of one of the first and largest UK reference datasets in children, which has transformed pediatric practice in the United Kingdom. She championed the clinical application of quantitative computed tomography in adults and children. She was a champion of the International Osteoporosis Foundation Vertebral Fracture initiative. Through her role in the European Society for Skeletal Radiology, Judy provided a bridge between the radiology and bone fields.

In collaboration with her colleagues in Manchester, Judy conducted research on vitamin D research studies that evaluated the effects of vitamin D and its active metabolite (1,25-dihydroxyvitamin D) on bone mass, bone geometry, and muscle function across the life course in different populations, particularly the South Asian population of the North-West United Kingdom. Judy also collaborated on studies evaluating the role of vitamin D on muscle function and sarcopenia in adults and children. Her mobile densitometry unit of which she was extremely proud facilitated much of this work across Greater Manchester, UK. She was also involved in research studies and intervention trials of vitamin D in chronic illnesses including cystic fibrosis, chronic renal failure, and coeliac disease. She also used her CT imaging expertise to study spinal canal stenosis and cord compression and thickening of the petrous bone, resulting in deafness in adults with chronic osteomalacia secondary to X-linked hypophosphatemia. In summary, Judy's contributions to vitamin D research have helped advance our understanding of the importance of this nutrient in various populations and chronic health conditions.

The UK Bone Research Society honored Judy by giving her the Dent Award in 2015, in recognition of her contribution to clinical imaging. In 2016, she was awarded the Linda Edwards Award from the Royal Osteoporosis Society, UK, for her outstanding contribution to the Society and to the field of osteoporosis. For radiology, she was awarded the Gold Medal from both the Royal College of Radiologists (2016) and the International Skeletal Society (2007).

Judy was a warm, thoughtful, and loyal friend. She was a great mentor to both of us and many other clinicians and scientists who are indebted to her mentorship and tutelage. Her collaborations spanned the globe. She will be fondly remembered by all for her elegance, her smile and her laugh, her bright clothes, and her endless energy and enthusiasm. Judy was wonderful company both professionally and personally. Outside of work, she loved culture, from Manchester United through to opera, flowers, gardening, and travel. Sadly Judy's husband of 45 years, Professor Peter Adams, an Emeritus Professor of Medicine at the University of Manchester, passed away a week later. They are survived by their two sons, Charles and James, and their grandchildren on whom they doted.

*Professor Kate Ward, MRC Lifecourse Epidemiology  
Centre, University of Southampton,  
Southampton, UK*

*Professor Zulf Mughal, Department of Paediatric  
Endocrinology,  
Royal Manchester Children's Hospital, Manchester  
University NHS Foundation Trust,  
Manchester, UK*

#### Heide S. Cross (1942–2021)

In 2021, we lost Heide S. Cross, one of the pioneers in vitamin D research, whose goal was to understand the role of vitamin D in cancer, with a main focus on colorectal cancer. Inspired by reports from C. F. Garland and his colleagues—that the risk of colorectal cancer significantly correlates with low vitamin D status as well as nutritional calcium deficit—Heide initiated a

series of studies to elucidate the cellular and molecular mechanisms by which vitamin D—through its hormonally active metabolite 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>)—and calcium could inhibit cell growth and promote differentiation in human colon cancer cells.

Heide identified the key elements in colon tumor cell-specific antiproliferative signaling from both the 1,25(OH)<sub>2</sub>D<sub>3</sub>-activated vitamin D receptor (VDR) as well as from the extracellular calcium-sensing receptor (CaSR), providing for the first time a valid molecular explanation for the well-known preventive effect of calcium in combination with vitamin D against the development of colon tumors. Heide and her group were also the first who discovered that human colon carcinoma cells are an important site of extrarenal expression of the CYP27B1-encoded enzyme 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase, and therefore are able to produce 1,25(OH)<sub>2</sub>D<sub>3</sub> from circulating 25-hydroxyvitamin D<sub>3</sub> (25(OH)D<sub>3</sub>). She has shown that calcium influences vitamin D metabolism in a cell-specific way, which is highly relevant for the antiproliferative effect of the mineral on colon epithelial cells. Unlike in renal cells, where calcium upregulates expression of the 25-hydroxyvitamin D-24-hydroxylase (CYP24A1), in colonocytes, the mineral ion suppresses expression and activity of the enzyme. Therefore, adequate calcium nutrition must be seen as an important means to counteract catabolism of 1,25(OH)<sub>2</sub>D<sub>3</sub> to maintain the intracellular concentrations of the steroid hormone at a level sufficiently high for effective control of cell growth.

The important finding that expression of CYP27B1 as well as of the VDR rises in parallel with tumor

progression through the adenoma/carcinoma sequence led her to formulate the theory that human colon tumor cells can activate intracellular signaling from the 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR complex as an intrinsic defense system against mitogenic stimuli of all sorts. This concept was shown to be valid also for other human malignancies such as breast and prostate cancer. Through the work of Heide, it has become possible to provide a molecular and cellular explanation for the numerous observations from epidemiological and clinical studies suggesting that deficiency and insufficiency of both vitamin D and calcium is a major risk factor for colorectal cancer and other malignancies.

In addition to her highly recognized scientific achievements, Heide was a teacher and mentor for numerous young scientists at the Medical University of Vienna. It was very important to her that her students gain experience abroad, which she made possible through her many collaborators at renowned institutes such as Johns Hopkins University, Cornell University, Brown University, and Harvard University.

In her private life, Heide was very interested in art and culture. She loved ballet and took dancing lessons after retiring, enjoying the freedom to follow her interests. Shortly after her retirement, Heide had enrolled to study the history of religion at the University of Vienna, in order to, as she said, “understand the world better.” She loved nature and traveling, and spent ever longer periods on the beautiful island of Karpáthos (Greece) every year. We shall miss her dearly.

*Enikő Kallay with input from Meinrad Peterlik and Heide's sister, Helga Lesigang*

# Preface to the fifth edition

---

The fifth edition of this textbook on vitamin D represents a landmark in that it is the first edition to be published in the “second century” of vitamin D. 2022 represents the generally accepted 100th anniversary of the first formal reference to vitamin D by Elmer McCollum. The editorial team and I hope that this new edition provides a comprehensive statement on the many advances that have occurred over 100 years of vitamin D research. It covers the fundamental information essential to our understanding of vitamin D—the photobiology that underpins synthesis of vitamin D, the metabolic pathways that enable generation of active metabolites of vitamin D and, of course, the skeletal disorders of vitamin D deficiency that sparked its discovery in 1922. These core features remain at the heart of the Vitamin D book, but are enhanced by new images, references and, in some cases, dramatic new developments such as alternative pathways that generate novel vitamin D metabolites with diverse biological properties ([Chapter 6, \*Alternative Pathways for Vitamin D Metabolism\*](#)). However, “Vitamin D” is much more than a core reference work and the editorial team (Roger Bouillon, Ed Giovannucci, David Goltzman, Mark Myer and JoEllen Welsh) and I have sought to present the ever widening impact of vitamin D on human (and non-human in the case of [Chapter 83, \*Vitamin D and Companion Animals\*](#)) health. In the 5 years since publication of the previous edition, the vitamin D research landscape has changed dramatically. This is to be expected for almost any facet of biomedical science, and research in general welcomes change. The vitamin D research field has embraced emerging technologies such as single cell OMICs and mass spectrometry imaging that have provided new perspectives on the mechanism of action of vitamin D. The expanding role of vitamin D in overall health and wellness has spurred multiple large supplementation trials, and the newest trials have been designed to build on lessons learned from earlier studies. The combined effect is a much clearer picture of how vitamin D functions and the most likely health benefits of vitamin D supplementation. In [Chapter 1 \(\*Historical Overview\*\)](#), the previous editors of “Vitamin D”, David Feldman and Wesley Pike provide a synopsis of the many new developments in the field, and which chapters detail these findings within each volume.

When considering the new developments in vitamin D biology, one obvious event that has been very prominent is the COVID-19 pandemic. Beyond the huge impact on healthcare and economies around the globe, COVID-19 brought substantial challenges to research that continue to be felt today. However, the COVID-19 pandemic had a particular resonance with vitamin D research. Very early in the pandemic, it was recognized that those individuals at greatest risk of infection and mortality from COVID-19 were in populations known to experience a high prevalence of vitamin D deficiency. Consequently, the pandemic generated a renewed and broader interest in the immunomodulatory properties of vitamin D and an explosion of publications on vitamin D status and COVID-19. The potential benefits of vitamin D for immune health in general and COVID-19 in particular remain unclear, in part because of the rapid implementation of vaccination programs at the end of 2020. Nevertheless, this new edition of “Vitamin D” reflects the changing landscape on vitamin D and infectious disease, with more chapters on various facets of immunity—notably dedicated chapters for *Vitamin D and Antiviral Immunity* ([Chapter 95](#)) and *Vitamin D and COVID-19* ([Chapter 99](#)).

Although the 5 years since the last edition of this book have witnessed a dramatic expansion of research on and public awareness of vitamin D, the passage of time has also seen the loss of several prominent vitamin D researchers. The deaths of six giants of vitamin D research—Judy Adams, Graham Carter, Heide Cross, Helen Henry, Ron Horst, and Tony Norman—are commemorated in dedicated memorials at the beginning of each volume of the book. The world of vitamin D is poorer without them. Recent years have also seen the passing of Roxanne Hall who was a fundamental part of the vitamin D world in her role as a meeting coordinator for the Vitamin D Workshop from 2012 to 2019. For both junior and established vitamin D researchers, including many authors of chapters in this book, Roxanne was a key facilitator for the annual conference and an integral part of the vitamin D community. In particular, she was the go-to person for all early career vitamin D researchers! Roxanne will be greatly missed. On a personal note, the beginning of 2023 brought the sad news of the

death of Louisa Jeffery a talented vitamin D researcher at Birmingham who worked with myself, Karim Raza and David Sansom. Louisa was younger and less well known than those remembered in the “In Memoriam” section. Nevertheless, she was a devoted vitamin D researcher who published 13 papers on vitamin D and immune function, including three seminal studies on T cell function, and she played a pivotal role in a new chapter on *Vitamin D and Rheumatoid Arthritis* (Chapter 103).

Completing this new edition of “Vitamin D” has involved a considerable effort by authors and editors under very difficult circumstances. Most of the chapters

were commissioned during periods of pandemic lockdown when contributors had conflicting demands and many other things on their minds. I salute everyone who has given their time and effort so generously over the 2 years, it has taken to complete the 106 chapters. I hope that “Vitamin D” will provide inspiration to a new generation of researchers, and that it will also serve to illustrate that the vitamin D research community is alive and well 100 years after its birth.

**Martin Hewison, PhD, Editor-in-Chief**

# List of abbreviations

---

1,25(OH) <sub>2</sub> D <sub>3</sub>	1 $\alpha$ ,25-Dihydroxyvitamin D <sub>3</sub>	ATP	Adenosine triphosphate
1,25(OH) <sub>2</sub> D	1 $\alpha$ ,25-Dihydroxyvitamin D	ATRA	All- <i>trans</i> -retinoic acid
1 $\alpha$ -(OH)D <sub>3</sub>	1 $\alpha$ -Hydroxyvitamin D <sub>3</sub>	AUC	Area under the curve
20(OH)D <sub>3</sub>	20-hydroxyvitamin D <sub>3</sub>	BARE	Bile acid response element
24(OH)L <sub>3</sub>	24-hydroxylumisterol <sub>3</sub>	Bax	BCL-2 associated X protein
24,25(OH) <sub>2</sub> D <sub>3</sub>	24,25-Dihydroxyvitamin D <sub>3</sub>	BB	Biobreeding
24,25(OH) <sub>2</sub> D	24,25-Dihydroxyvitamin D	BCa	Breast cancer
25(OH)D <sub>3</sub>	25-Hydroxyvitamin D <sub>3</sub>	BCC	Basal cell carcinoma
25(OH)D	25-Hydroxyvitamin D	Bcl-2	B cell CLL/Lymphoma 2
5-ASA	5-Aminosalicylic acid	Bcl-xl	B cell lymphoma-extra large
7-DHC	7-Dehydrocholesterol	BECN1	Beclin 1
9- <i>cis</i> -RA	9- <i>cis</i> -retinoic acid	BER	Base excision repair
[Ca <sup>2+</sup> ]	Internal calcium ion molar concentration	bFGF	Basic fibroblast growth factor
AA	Arachidonic acid	BFU	Burst-forming unit
AC	Adenylyl cyclase	BGP	Bone Gla protein (osteocalcin)
ACE	Angiotensin-converting enzyme	BHMT	Betaine-homocysteine methyltransferase
ACF	Activation frequency	BLM	Basal lateral membrane
ACTH	Adrenocorticotropin	B <sub>max</sub>	Maximum number of binding sites
ADH	Antidiuretic hormone (vasopressin)	BMC	Bone mineral content
ADHR	Autosomal dominant hypophosphatemic rickets	BMD	Bone mineral density
ADP	Adenosine diphosphate	BMI	Body mass index
AHO	Albright's hereditary osteodystrophy	BMP	Bone morphogenetic protein
AI	Adequate intake	BMU	Basic multicellular unit
AIDS	Acquired immunodeficiency syndrome	bp	Base pairs
Aj.AR	Adjusted apposition rate	BPH	Benign prostatic hyperplasia
Akt	RAC- $\alpha$ serine/threonine-protein kinase	BRAF	v-Raf murine sarcoma viral oncogene homolog B
AKT	Acutely transforming retrovirus AKT8 in rodent T-cell lymphoma	BRD	Bromodomain containing
ALK	Anaplastic lymphoma kinase	BSA	Bovine serum albumin
ALP	Alkaline phosphatase	BUA	Bone ultrasound attenuation
Alum	Aluminum hydroxide	c-MET	Mesenchymal-epithelial transition factor
ANG II	Angiotensin II	CaBP	Calcium-binding protein
ANP	Atrial natriuretic peptide	CAD	Coronary artery disease
AOM	Azoxymethane	CaM	Calmodulin
AP	Apurinic/aprimidinic	CAMP	Cathelicidin antimicrobial peptide
APC	Antigen-presenting cell	cAMP	Cyclic AMP
APD	Aminohydroxypropylidene bisphosphonate	CaSR or CaR	Calcium-sensing receptor
APL	Atrichia with papular lesions	CAT	Chloramphenicol acetyltransferase
AR	Androgen receptor	CBG	Corticosteroid-binding globulin
ARC	Activator-recruited cofactor	CBP	Competitive protein-binding assay
ARE	Androgen responsive element	CC	Chief complaint
ATAC-seq	Assay for Transposase-Accessible Chromatin using sequencing	CCL2	C-C Motif Chemokine Ligand 2
ATF-4	Activating transcription factor 4	CCL5	C-C Motif Chemokine Ligand 5
ATG5	Autophagy-related 5	CD	Crohn's disease
ATM	DNA strand sensor protein kinase	CDCA	Chenodeoxycholic acid
		CDH1	E-cadherin
		CDK or Cdk	Cyclin-dependent kinase

cDNA	Complementary DNA	DBP	Diastolic blood pressure
CDP	Collagenase-digestible protein	DBP	Vitamin-D-binding protein
Cdx-2	Caudal-related homeodomain protein	DC	Dendritic cell
CEBP	CCAAT enhancer binding protein	DCA	Deoxycholic acid
CFU	Colony-forming unit	DCIS	Ductal carcinomas in situ
cGMP	Cyclic GMP	DCT	Distal convoluted tubule
CGRP	Calcitonin gene-related peptide	DDB1	XPE-binding factor
CHB	Chronic hepatitis B	DDB2	DNA Damage Binding protein 2
CHC	Chronic hepatitis C	DEK	DEK proto-oncogene
CHF	Congestive heart failure	DEQAS	Vitamin D external quality assessment scheme
ChIA-PET	Chromatin interaction analysis by paired-end tag sequencing	DEXA or DXA	Dual energy X-ray absorptiometry
ChIP-seq	Chromatin immunoprecipitation and sequencing	DHEA	Dehydroepiandrosterone
ChIP	Chromatin immunoprecipitation	DHT	Dihydrotachysterol or dihydrotestosterone
CHOP	C/EBP homologous protein	DIC	Disseminated intravascular coagulation
CK-II	Casein kinase II	DIDS	Disodium 4,4'-diisothiocyanatostilbene-2,2'-disulfonate (DIDS)
CK1	Casein kinase 1	DIKKOPF-1	Dickkopf-related protein 1
CLIA	Competitive chemiluminescence immunoassay	DIPP	Type 1 Diabetes Prediction and Prevention study
Cm. Ln.	Cement line	DMR	Differentially methylated region
cM	Centimorgans	DMSO	Dimethyl sulfoxide
CMM	Cutaneous malignant melanoma	DNase-seq	DNase I hypersensitivity sequencing
CMV	Cytomegalovirus	DNMT	DNA-methyltransferase
CNS1	Conserved noncoding sequence-1	DR	Direct repeat
CNS	Central nervous system	DRIP	Vitamin D receptor interacting protein
CoA	Co-activator	DSP	Dental sialoprotein
CoR	Co-repressor	DSS	Dextran sodium sulfate
COX	Cyclooxygenase	E <sub>1</sub>	Estrone
CP	Chronic pancreatitis	E <sub>2</sub>	Estradiol
CPBA	Competitive protein-binding assay	EAE	Experimental autoimmune encephalitis
CPD	Cyclobutane pyrimidine dimers	EBT	Electron beam computed technology
cpm	Counts per minute	EBV	Epstein–Barr virus
CRE	cAMP response element	EC <sub>50</sub> or ED <sub>50</sub>	Effective concentration (dose) to cause 50% effect
CREB	cAMP response element binding protein	EC	Endothelial cells
CRF	Chronic renal failure	ECaC	Epithelium calcium channel
CsA	Cyclosporin A	ECF	Extracellular fluid
CSF	Colony-stimulating factor	EDTA	Ethylenediaminetetraacetic acid
CT	Calcitonin or computerized tomography	EFTUD1	Elongation factor like GTPase 1
CTCF	CCCTC-binding factor	EGF	Epidermal growth factor
CTLA-4	Cytotoxic T-lymphocyte antigen 4	EGFR	Epidermal growth factor receptor
CTR	Calcitonin receptor	ELISA	Enzyme-linked immunosorbent assay
CTX	Cerebrotendinous xanthomatosis	EMSA	Electrophoretic mobility shift assay
CTX	Cyclophosphamide	EMT	Epithelial-mesenchymal transition
CVC	Calcifying vascular cell	ENCODE	Encyclopedia of DNA elements
CXCL10	C-X-C motif chemokine ligand 10	EP <sub>1</sub>	PG receptor-1
CYP24A1	Cytochrome P450, 24-hydroxylase	ER	Endoplasmic reticulum
CYP27A1	Cytochrome P450, 25-hydroxylase	ER	Estrogen receptor or endoplasmic reticulum
CYP27B1	Cytochrome P450, 1 $\alpha$ -hydroxylase	ERBB2	erb-b2 receptor tyrosine kinase 2
CYP2R1	Cytochrome P450, 25-hydroxylase	ERE	Estrogen response element
CYP	Cytochrome P450	ERK	Extracellular signal-regulated kinase
DAG	Diacylglycerol	ERp57	Endoplasmic reticulum protein 57
DAISY	Diabetes AutoImmunity Study in the Young	ER $\alpha$	Estrogen receptor alpha
DBD	DNA-binding domain	Et	Endothelin

F	Tumor necrosis factor	HGF	Hepatic growth factor
FACS	Fluorescence-activated cell sorting or sorter	Hh	Hedgehog
FAD	Flavin adenine dinucleotide	HHRH	Hereditary hypophosphatemic rickets with hypercalciuria
FAIRE-seq	Formaldehyde-assisted isolation of regulatory elements sequencing	HIF-1	Hypoxia-inducible factor 1
FCS	Fetal calf serum	HIV	Human immunodeficiency virus
FDA	US Food and Drug Administration	HL	1 $\beta$ ,25- dihydroxyvitamin D <sub>3</sub>
FFA	Free fatty acid	HLA-DR	Human leukocyte antigen DR
FIT	Fracture Intervention Trial	HLA	Human leukocyte antigen
FMTc	Familial medullary thyroid carcinoma	HNF	Hepatocyte nuclear factor
FOXA1	Forkhead box A1	HOMER	Hypergeometric Optimization of Motif EnRichment
FoxP3	Forkhead box P3	HPI	History of present illness
FP	Formation period	HPLC	High-performance liquid chromatography
FRAP	Fluorescence recovery after photobleaching	HPV	Human papilloma virus
FS	Fanconi syndrome	HR	Hairless
FSK	Forskolin	HRE	Hormone response element
FXR	Farnesoid X receptor	HSA	Human serum albumin
FZD	Frizzled receptor	HSC	hepatic stellate cells
G-CSF	Granulocyte colony-stimulating factor	Hsp	Heat-shock protein
G <sub>0</sub> , G <sub>1</sub> , G <sub>2</sub>	Gap phases of the cell cycle	HSV	Herpes simplex virus
g	Acceleration due to gravity	HVDRR	Hereditary vitamin-D-resistant rickets
g	Gram	HVO	Hypovitaminosis D osteopathy
GABP $\alpha$	GA binding protein transcription factor $\alpha$	i.m.	Intramuscular
GAD65	Glutamic acid decarboxylase 65-kDa	i.p.	Intraperitoneal
GADD45	Growth arrest and DNA damage inducible	i.v.	Intravenous
GAG	Glycosaminoglycan	IA-2	Islet antigen 2
GC-MS	Gas chromatography–mass spectrometry	IBD	Inflammatory bowel disease
GDF15	growth/differentiation factor-15	IBMX	Isobutylmethylxanthine
GDNF	Glial-cell-derived neurotrophic factor	IC <sub>50</sub>	Concentration to inhibit 50% effect
GFP	Green fluorescent protein	ICA	Intestinal calcium absorption
GFR	Glomerular filtration rate	ICMA	Immunochemiluminometric assay
GH	Growth hormone	ICOS	Inducible T-cell costimulator
GHRH	Growth-hormone-releasing hormone	IDBP	Intracellular vitamin-D-binding protein
GIO	Glucocorticoid-induced osteoporosis	IDDM	Insulin-dependent diabetes mellitus
Gli1	Glioma-associated oncogene homolog	IDH1	Isocitrate dehydrogenase 1
GM-CSF	Granulocyte-macrophage colony-stimulating factor	IDM	Infants of diabetic mothers
GnRH	Gonadotropin-releasing hormone	IEL	Intraepithelial cells
GR	Glucocorticoid receptor	IFN	Interferon
GRE	Glucocorticoid response element	Ig	Immunoglobulin
GRTH	Generalized resistance to thyroid hormone	IGF-IR	IGF-I receptor
GSH	Glutathione	IGF	Insulin-like growth factor
GSK	Glycogen synthase kinase 3	IGFBP	IGF-binding protein
GWAS	Genome-wide association study	IGV	Integrative Genomics Viewer
h	Hour	IKK $\beta$	I kappa B kinase beta
HAT	Histone acetyltransferase	IL	Interleukin (e.g., IL-1, IL-1 $\beta$ , etc.)
HB	Hepatitis B	IMCaI	Intestinal membrane calcium-binding complex
hCAP-18	human cationic antimicrobial protein	iNKT	Invariant NKT
HCC	hepatocellular carcinoma	iNOS	Inducible nitric oxide synthase
HCV	chronic hepatitis C virus	IP <sub>3</sub>	Inositol trisphosphate
HCY	Homocysteine	IRMA	Immunoradiometric assay
HDAC	Histone deacetylase	IU	International units
HEK	Human embryonic kidney		

IUPAC International Union of Pure and Applied Chemists	MET Methionine
I $\kappa$ B Inhibitor of nuclear factor kappa B	MGP Matrix Gla protein
JAK Janus kinase	MHC Major histocompatibility complex
JG Juxtaglomerular	min Minute
JNK c-Jun NH <sub>2</sub> -terminal kinase	MIU Million international units
JNK c-Jun N-terminal kinase	MK/TEI (23S)-25-dehydro-1 $\alpha$ -OH-D3-26,23-lactone
kb Kilobases	MKP5 Mitogen-activated protein kinase phosphatase 5
kbp Kilobase pairs	MLR Mixed lymphocyte reaction
Kd Dissociation constant	Mlt Mineralization lag time
kDa Kilodaltons	MMF Mycophenolate mofetil
KDM Lysine demethylase	MMP Matrix metalloproteinase
Keap1 Kelch-like ECH-associated protein	MR Mineralocorticoid receptor
K <sub>m</sub> Michaelis constant	MRI Magnetic resonance imaging
KMT Lysine methyltransferase	mRNA Messenger ribonucleic acid
KO Knockout	MRP4 Multidrug resistance-associated protein 4
KRA Kirsten ras oncogene homolog	MS Multiple sclerosis
KRAS V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog	MT Metric ton
LADA Latent autoimmune diabetes in adults	MTC Medullary thyroid carcinoma
LBD Ligand-binding domain	MTHFR N,N-methylene-tetrahydrofolate reductase
LC-MS/MS Liquid chromatography tandem mass spectrometry	mTOR Mammalian target of rapamycin
LCA Lithocholic acid	NADH Nicotinamide adenine dinucleotide
LDL Low-density lipoprotein	NADPH Nicotinamide adenine dinucleotide phosphate
LDLRAP1 Low-density lipoprotein receptor adaptor protein 1	NAF Nuclear accessory factor
Lef Lymphoid enhancer factor	NAFLD Nonalcoholic fatty liver disease
LFNG LFNG O-fucosylpeptide 3-beta-N-acetylglucosaminyl transferase	NASH Nonalcoholic steatohepatitis
Li. Ce Lining cell	NBT Nitroblue tetrazolium
LIF Leukemia inhibitory factor	NcAMP Nephrogenous cAMP
LNH Late neonatal hypocalcemia	NCCN National Comprehensive Cancer Network
LOD Logarithm of the odds	NCP Noncollagen protein
LPR6 Low-density lipoprotein receptor 6	NER Nucleotide excision repair
LPS Lipopolysaccharide	NF $\kappa$ B Nuclear factor kappa B
LSCC Lung squamous cell carcinoma	NGF Nerve growth factor
LT Leukotriene	NHANES III National Health and Nutrition Examination Survey III
LUAD Lung adenocarcinoma	NHL Non-Hodgkin's lymphoma
LXR Liver X receptor	NIDDM Noninsulin-dependent diabetes mellitus
M-CSF Macrophage colony-stimulating factor	NIH National Institutes of Health
M Mitosis phase of cell cycle	NK cell Natural killer cell
M Molar	NLS Nuclear localization signal
Mab Monoclonal antibody	NMR Nuclear magnetic resonance
MAPK Mitogen-activated protein kinase	NOD Nod-like
MAR Matrix attachment region	NOD Nonobese diabetic
MAR Mineral apposition rate	NPT Sodium/phosphate cotransporter
MARRS Membrane-associated rapid response steroid	NR Nuclear receptor
MBP Myelin basic protein	Nrf2 Nuclear factor-erythroid-2-related factor 2
MCR Metabolic clearance rate	NSCLC Non-small-cell lung cancer
MEK Mitogen-activated ERK kinase	Ob Osteoblast
MEN2 Multiple endocrine neoplasia type 2	Oc Osteocalcin or osteoclast
	OCIF Osteoclastogenesis inhibitory factor (same as OPG)
	OCT 22-Oxacalcitriol
	ODF Osteoclast differentiation factor (same as RANKL)

OHO	Oncogenic hypophosphatemic osteomalacia	PLA <sub>2</sub>	Phospholipase A <sub>2</sub>

# Defining thresholds for vitamin D I: scientific rationale for serum 25-hydroxyvitamin D cutoffs of 25 and 50 nmol/L

*Andrea L. Darling and Susan A. Lanham-New*

Nutrition, Food and Exercise Sciences Department, School of Biosciences, Faculty of Health and Medical Sciences,  
University of Surrey, Guildford, United Kingdom

## OBJECTIVES

- To discuss the case for the use of the 25 nmol/L cutoff, with particular relevance for ensuring musculoskeletal health.
- To discuss the case for the use of the 50 nmol/L cutoff, with particular relevance for ensuring cellular health, including adequate immune function and prevention of cancer.
- To discuss the needs of specific population groups (e.g., those from ethnic minority groups, older people, those with certain health conditions, those taking certain medications, and those pregnant or lactating) who may have difficulties in meeting desirable 25(OH)D concentration due to lifestyle, health, or physiological factors, or who may even require a different 25(OH)D threshold.
- To discuss the issues surrounding meaningful definition of thresholds for vitamin D.

## 1. Introduction

There has been intense debate regarding the required level of serum or plasma 25-hydroxyvitamin D (25(OH)D), which must be achieved, in humans, to avoid vitamin D deficiency and insufficiency, as well as to provide optimal health for all tissue types. In this chapter,

the evidence for setting the thresholds of 25 and 50 nmol/L will be put forward, including the current recommendations by institutions such as the US Institute of Medicine (IOM) [1], the European Food Standards Agency (EFSA) [2], and the UK Scientific Advisory Committee on Nutrition (SACN) [3]. The chapter will also discuss special considerations for some population groups in meeting 25(OH)D thresholds, including ethnic minorities, older individuals, those who are pregnant or lactating, and those with certain health conditions or medications. Issues affecting the ability to derive meaningful thresholds will also be discussed.

## 2. Justification for serum 25(OH)D concentration >25 nmol/L

### 2.1 The UK scientific advisory committee on nutrition

In 2016, SACN recommended that the UK population should have a 25(OH)D concentration above 25 nmol/L throughout the year [3]. They highlighted that some population groups may be at particular risk of having 25(OH)D < 25 nmol/L due to low summer sun exposure, having darker skin, or wearing clothes that cover the skin year-round [3]. Recommending a sun exposure for the whole population was deemed not possible due to the complexity of this requirement considering the wide range of factors affecting vitamin D status [3].

In terms of vitamin D intake, SACN proposed a reference nutrient intake (RNI) of 10 µg per day, year-round, for those aged 4 years and over, which would ensure 25(OH)D concentrations over 25 nmol/L in 97.5% of the population, when sun exposure is minimal [3]. Safe intakes were recommended for those under 4 years, as there was not enough data in these age groups to calculate RNIs [3]. Specifically, these were as follows: 8.5–10 µg per day (age 0–1 year, as well as breastfed [partially or exclusively] infants from birth); 10 µg per day (ages 1–4 years) [3]. It was recognized by SACN (2016) [3] that 10 µg is difficult to achieve from diet alone and that other strategies should be considered to enable the population to meet these required intakes [3].

The recommendation for >25 nmol/L (and the concordant RNIs and safe intakes required to achieve this) was based on the requirements for 25(OH)D to ensure adequate musculoskeletal health in both adults and children [3]. SACN deemed that there was not enough evidence, including that from randomized control trials, regarding nonmusculoskeletal health outcomes. Of note, this differed from the approaches taken by the EFSA [2] and the Nordic Guidelines [4], whereby at least one nonmusculoskeletal outcome was used to ascertain required 25(OH)D cutoffs.

In terms of nonmusculoskeletal health outcomes, evidence was systematically reviewed, but not used in the decision-making regarding the final threshold chosen. These health outcomes included reproductive health (maternal and child outcomes), cardiovascular disease, hypertension, cancer, immune modulation, neuropsychological functioning, infectious diseases, oral health, all-cause mortality, and age-related macular degeneration. For pregnancy, links between gestational diabetes with 25(OH)D were unclear, but some randomized control trials suggested vitamin D, in combination with calcium, may reduce the risk of preeclampsia [3]. In terms of cancer, with the exception of colorectal sites, there was no strong association between 25(OH)D and cancer risk. Moreover, few randomized controlled trials conducted showed no effect of vitamin D supplementation on cancer risk [3]. For CVD, although cohort studies showed a reduced risk of CVD with increased 25(OH)D, intervention trials showed no association [3]. For hypertension, cohort and cross-sectional studies showed a negative association between 25(OH)D and hypertension, but randomized control trial metaanalyses showed inconsistent results [3]. For all-cause mortality, observational studies suggested a negative association between mortality and serum 25(OH)D, but a systematic review of randomized control trials showed no effect of vitamin D intake or vitamin D status on mortality [3]. In terms of

immunity, cohort studies on asthma and other atopic disorders gave inconsistent findings, and there was little evidence that vitamin D supplementation had any effect on risk of developing autoimmune disease [3]. There was little evidence assessing the risk of developing type 1 diabetes, rheumatoid arthritis, inflammatory bowel disease, and systemic lupus erythematosus (SLE) [3], and evidence for the link between serum 25(OH)D and multiple sclerosis was inconsistent [3]. For respiratory tract infections (RTIs), cohort studies suggested an inverse association with 25(OH)D risk, with thresholds for increased risk at either <25 nmol/L or <50 nmol/L [3]. There was little evidence to support a link between 25(OH)D and mental health with some studies being of ecological design [3]. There was some evidence that oral health is linked to 25(OH)D, potentially via effects on tooth structure, but for periodontal disease, it was suggested that it may partly be via associations between 25(OH)D and immune health [3]. Finally, there were no studies on the association between 25(OH)D and age-related macular degeneration [3].

For musculoskeletal health, SACN was not able to discern, based on current evidence, a threshold below which rickets occurs ([3]). However, in most case reports and other observational studies, 25(OH)D was <25 nmol/L, and this was used to support the cut-off of 25 nmol/L for musculoskeletal health, for the purposes of population health [3]. It was acknowledged that this is not a specific clinical diagnostic threshold [3]. In terms of osteomalacia, most data were from case reports and two cross-sectional studies, with 25(OH)D ranging from 4 to 20 nmol/L [3], again supporting a threshold of 25 nmol/L for musculoskeletal health.

Conversely, some evidence suggested that a 25(OH)D higher than 25 nmol/L is required for skeletal health [5], with a higher requirement of at least 50 nmol/L predicted to ensure that 97.5% of the population is protected against osteomalacia [5], and potentially even 75 nmol/L required to fully mineralize bone tissue [5]. However, this was based on the amount of osteoid in bone from biopsies taken during postmortem examinations and correlated with past 25(OH)D status measurements from medical records. Therefore, the 25(OH)D result was not necessarily accurate for the time of death. Critique of the limitations of using postmortem bone data has been given in more detail by Aspray and Francis (2013) [6], and the results from the postmortem study were not considered reliable enough data by SACN to steer the decision toward 50 nmol/L as the cutoff for musculoskeletal health. This is in contrast to the decision-made by the US IOM [1], who considered the postmortem data [5] sufficient evidence for supporting the 50 nmol/L cutoff for musculoskeletal health.

**FIGURE 51.1** IOM: Conceptualization of integrated bone health outcomes and vitamin D exposure. Bone; calcium; 25(OH)D, 25-hydroxyvitamin D. Source: IOM report [1], page 368. Reproduced with permission from the National Academies Press.

### 3. Justification for serum 25(OH)D concentration >50 nmol/L

#### 3.1 The US/Canada Institute of Medicine

A 25(OH)D concentration greater than 50 nmol/L for population health has been recommended by the US IOM [1], and EFSA [2], as well as the Nordic guidelines [4]. The cutoff of 50 nmol/L was based on three main threads of evidence for ensuring bone health, assuming adequate calcium intake (Fig. 51.1). First, risk of rickets is minimized when 25(OH)D status is between 30 and 50 nmol/L [1]. Second, randomized trials and observational studies assessing adult fracture risk suggest a 25(OH)D status of 40–50 nmol/L is required to reduce fracture risk, albeit some studies noted that 60–70 nmol/L was superior [1]. Third, the postmortem data, as discussed before, support a threshold of at least 50 nmol/L [1,5]. The focus on skeletal health was due to the lack of evidence of other health outcomes, as judged by the IOM Committee.

The IOM used the principle that 25(OH)D concentration is correlated to vitamin D intake, so intake data are useful in simulating dose–response curves when sun exposure is low [1]. This was then used to estimate the intake required to maintain population 25(OH)D at the level that modeling suggested was required for bone health (50 nmol/L) [1] (Fig. 51.2).

The IOM based their dietary reference intakes (DRIs) on achieving 50 nmol/L to cover the needs of 97.5% of

the population, and set Recommended Dietary Allowances (RDAs) for those aged over 1 year and adequate intakes (AIs) for those aged 1 year or younger [1]. The IOM noted a lack of dose–response intervention trials in the literature base, with most trials being only single dose, and often not reporting background dietary intake of vitamin D [1]. In addition, many trials supplemented both vitamin D and calcium, so it was difficult to assess the separate effects of each nutrient separately on the health outcome being assessed [1]. The DRIs for vitamin D were based on those required when calcium was adequate and sun exposure was minimal [1]. The criteria of minimal sun exposure were important as UVB exposure is such a complex construct, and there was reluctance to assume a certain degree of sun exposure when setting dietary requirements [1]. The AI for infants aged up to 12 months was set as 400IU/d, with an RDA of 600IU/d for those aged 1–70 years, and an RDA of 800IU/d for the over seventies. For pregnancy and lactation, 600IU/d was set as the RDA.

The IOM report presented tolerable upper intake levels (UL) for different life stages as follows: 1000 IU (25 µg) per day for age 0–6 months, 1500 IU (38 µg) per day for age 6–12 months, 2500 IU (63 µg) per day for age 1–3 years, 3000 IU (75 µg per day) for age 4–8 years, and 4000 IU (100 µg) per day for 9 years and older [1].

A plethora of research articles supporting the 50 nmol/L cutoff have been published since the release of the IOM report, including in relation to

**FIGURE 51.2** The relation between serum 25-hydroxyvitamin D [25(OH)D] concentrations (in late winter 2007) and total vitamin D intake (diet and supplemental) in 20- to 40-year-old healthy persons ( $n = 215$ ) living at northerly latitudes ( $51$  and  $55^{\circ}\text{N}$ ). Mean response and 95% CIs in the shaded area. Vitamin D intake; dietary vitamin D; 25(OH)D, 25-hydroxyvitamin D. Source: Cashman et al. [7]. Copyright (2008), with permission from Elsevier.

nonmusculoskeletal outcomes. Indeed, it is possible that a higher 25(OH)D than 25 nmol/L is needed for health of other tissue types, including immune cells and general cell health to prevent cancer. For example, numerous studies have found a benefit for reduction of immune-associated disease when 25(OH)D  $> 50$  nmol/L, after controlling for key confounders, including pneumonia survival [8] and risk of developing acute respiratory tract infections [9–11]. In terms of cancer, studies have found 25(OH)D greater than 50 nmol/L was associated with higher breast cancer survival [12] and lower risk of colorectal cancer [13], albeit some studies have found that 75 nmol/L is more beneficial for reducing cancer risk, for example, the Longitudinal Aging Study Amsterdam [14]. For pregnancy-related outcomes, having maternal 25(OH)D  $> 50$  nmol/L has been associated with reduced risk of preeclampsia [15,16], and higher risk of adverse lung and neurocognitive development [17] as well as poorer bone outcomes [18] in the offspring.

For mortality, a recent paper using UK Biobank data in 365,530 participants, with no CVD, diabetes, or cancer history at baseline (2006–10), found reduced cancer-specific mortality with baseline 25(OH)D  $> 45$  nmol/L as well as reduced all-cause and CVD mortality with baseline 25(OH)D  $> 60$  nmol/L [19]. In addition, multiple studies show that the PTH suppression (plateau), associated with 25(OH)D, occurs at around 30–50 nmol/L [20,21]. Most recently, nonlinear Mendelian randomization studies have suggested vitamin D

status is causally linked to risk of CVD and all-cause mortality, with a leveling off of risk for both of these outcomes at around 50 nmol/L [22,23].

However, the methods used in the IOM report [1] have been criticized. The review by Heaney and Holick [24] highlights evidence favoring a cutoff of 75 nmol/L for bone health, citing evidence from randomized control trials, including metaanalyses of randomized control trials, which showed further fracture reduction after vitamin D supplementation up to 75 nmol/L [24]. Moreover, the review suggests a different interpretation of the Priemel et al. data [5], in which 75 nmol/L more closely matches the point at which bone osteoid is minimized. The review also points out that 600 IU does not align with the known rule of thumb for how vitamin D intake affects 25(OH)D (each extra 100 IU/d puts 25(OH)D up by 2.5 nmol/L) and the DRIs do not account for the fact the people with obesity need larger amounts of vitamin D than those without obesity [24].

As pointed out in another commentary [25], the IOM decision differs from recommendations given by international bodies such as the International Osteoporosis Foundation (IOF), who recommend 800–1000 IU/d for those aged 60 years and over, and see 75 nmol/L as the recommended 25(OH)D concentration to prevent falls and fractures [26]. This commentary [25] discusses how the IOF recommends 700–1000 IU/d for falls prevention [26], but the 50 nmol/L cutoff was still derived solely from bone health outcomes.

### 3.2 European food safety agency and nordic guidelines

When setting their recommendation in 2016, EFSA assumed minimal sun exposure and used serum 25(OH)D as their biomarker of vitamin D status [2]. The health outcomes they used to set the DRV included musculoskeletal and pregnancy-related outcomes, but not lactation-related health outcomes (due to a lack of a relationship with 25(OH)D) or other nonmusculoskeletal outcomes (due to insufficient evidence) [2]. The data suggested increased risk of adverse effects for both musculoskeletal health and pregnancy-related health below 50 nmol/L [2]. Using data from randomized control trials, they set an adequate intake (AI) of 15 µg per day for those aged 1 year and older and 10 µg per day for infants aged 7–11 months. The AI for pregnancy and lactation was 15 µg per day [2].

The Nordic Nutrition Recommendations (2012) [4] defined vitamin D insufficiency as 25(OH)D 30–50 nmol/L, and defining 50 nmol/L as the threshold for sufficiency. To achieve this in the population, they set a recommendation for 10 µg per day for ages for first weeks of life to age 74 years (no adjustment for pregnancy or lactation), and 20 µg per day for 75 years and older (increased relative to younger adults due to lesser ability to produce vitamin D in the skin, and due to evidence supporting use of vitamin D to prevent fractures and falls, as well as general mortality) [4]. People with little or no sun exposure were recommended 20 µg per day [4].

To summarize, the IOM, EFSA, and Nordic Guidelines all suggested 50 nmol/L as the desired 25(OH)D threshold. They all based their recommendations on the basis of systematic literature reviews, but differed in the health outcomes considered. It must be noted that there is some justification for considering higher thresholds, for example, the US Endocrine Society Guidelines recommend 75 nmol/L [27]. In support of this, in a recent study of Brazilian women, PTH plateaued at a 25(OH)D of 70–80 nmol/L [28], albeit the slope was still relatively flat at 50 nmol/L [28]. However, we will not discuss the 75 nmol/L threshold in detail here as it is discussed in a separate chapter in this book.

## 4. Issues with reaching 25(OH)D thresholds for specific groups

There is concern regarding the known high levels of vitamin D deficiency in darker-skinned ethnic minority groups. For example, research using the UK Biobank cohort has shown that 60% of the South Asian [29],

35% of the Black African [30], and 37% of the Black African Caribbean [30] groups (all data from 2006–10) had 25(OH)D less than 25 nmol/L. In the South Asian group of the UK Biobank, 23% of men and 39% of women took a vitamin D containing supplement (i.e., a single vitamin D supplement, and/or a multivitamin) [31]. Similar data have been found for 25(OH)D concentrations in Black and South Asian populations, living in Europe, the United States, Canada, and New Zealand [32–35]. Of concern, a recent study found that short, regular exposures to sunlight around midday in the Northern UK (53.5°N) were not enough to enable production of sufficient vitamin D in the skin of South Asian individuals [36]. Therefore, public health policies in high-latitude countries recommending short exposures to sunlight around midday, for vitamin D populations, may be insufficient for darker skinned groups.

Few data are available examining vitamin D requirements for ethnic minority groups, but a recent systematic review and metaanalysis of randomized control trials estimated that a daily intake of 67 µg per day would be required to keep Black and South Asian populations, living in high-latitude countries, above 50 nmol/L [37]. The authors discussed how this is above the current vitamin D intake recommendations by multiple international bodies and will mean that 2.5% of Black and South Asian persons at this intake would be > 158 nmol/L [37], a level that in supplementation trials has been associated with adverse effects [37]. This suggests that for some ethnic minority groups, a higher intake of vitamin D may be required to meet the 50 nmol/L threshold, albeit more research is required on this topic.

In addition, there is some suggestion that optimal thresholds for 25(OH)D may vary by ethnic group. Fig. 51.3 illustrates the inflection point (the 25(OH)D concentration at which PTH concentration stops rising and reaches a plateau), for Asian, Black, and White populations. There is some indication that PTH plateaus at a lower level in Asian and Black populations (35–70 nmol/L) than in White populations (50–150 nmol/L) albeit the ethnic difference shown are highly dependent on the CaMos study [38], with other studies showing a more similar plateau between ethnic groups.

The ability to produce 25(OH)D in the skin declines with aging, likely due to reduced production of previtamin D under the action of ultraviolet radiation [39] as well as a declined ability to hydroxylate 25(OH)D [40,41] (albeit it is unclear as to whether the latter is due to age per se, or due to age-associated comorbidities [40]). Therefore, older people may have higher requirements for vitamin D intake, or sunlight exposure, than

**FIGURE 51.3** Inflection points for PTH in relation to 25(OH)D by ethnicity. From El-Hajj Fuleihan, Rahme and Bassil in Burckhardt, Dawson-Hughes, and Weaver (Eds). Copyright (2013), with permission from Springer Nature.

do younger people. In addition, many older people, especially those who are frail and/or in nursing homes, have little outdoor sun exposure. For example, an Australian study found nursing home residents were at 1.8 times increased risk of 25(OH)D deficiency ( $<25$  nmol/L) compared with free-living individuals [42]. Forty-seven percent of the nursing home residents had low sun exposure ( $<35$  mJ/cm<sup>2</sup>) compared with none of the free-living individuals [42].

As with younger populations, older people are likely to consume little vitamin D from the diet. The UK National Diet and Nutrition Survey (2016–19) showed a median intake of 2.4 µg vitamin D per day from food in 19- to 64-year-olds, compared with 2.9 µg per day in persons aged 65 years and older [43]. The difference is likely to be larger when considering just frail older people living in nursing homes. To summarize, older people may have lifestyle factors meaning they may have less opportunity to produce vitamin D from the sun, as well as consume it in the diet.

There is a need to be cautious regarding high 25(OH)D concentrations in persons with certain medical conditions or physiological states. Vitamin D supplementation in patients with sarcoidosis may lead to the overproduction of 1,25(OH)D<sub>2</sub> by lung macrophages, leading to hypercalcemia and hypercalciuria [44]. Persons with obesity may have altered vitamin D requirements, compared with persons with less adiposity. For example, studies have found a lower 25(OH)D in

persons with obesity [45], which may be due to sequestering of 25(OH)D by adipose tissue [46], or due to volumetric dilution due to increased body size [47]. Randomized controlled trials show that persons with obesity require a higher intake of vitamin D, compared with persons without obesity, to achieve the same 25(OH)D concentration [48]. Therefore, higher vitamin D intake requirements, to achieve a certain threshold, may be required for persons with obesity.

Finally, some medications affect vitamin D metabolism, which may affect the vitamin D requirement to meet 25(OH)D sufficiency thresholds. Use of metformin may be associated with reduced 25(OH)D status [49]. Phenytoin and sodium valproate are known to interfere with the renal 25-hydroxylation of vitamin D, which cause a problem in producing circulating 25(OH)D [50]. Thiazide diuretics reduce calcium excretion in the urine, which theoretically could alter vitamin D metabolism, although a recent review found that use of thiazides did not alter 25(OH)D concentration [51]. There has been inconsistent evidence as to whether loop or potassium-sparing diuretics have a detrimental association with vitamin D and calcium metabolism [51]. Similarly, there is inconsistent evidence as to whether statin use is associated with 25(OH)D concentration [52].

Interindividual differences (e.g., genetics) may affect vitamin D metabolism. For example, single nucleotide polymorphisms (SNPs) in vitamin D-related genes may effect actual 25(OH)D concentrations, with some

individuals potentially developing very high 25(OH)D concentrations. SNPs may also effect the optimal threshold required for each individual, via difference in cellular and tissue function. The relative prevalence of individuals who more rapidly achieve higher 25(OH)D concentrations, given the same sunlight exposure and/or dietary intakes to other people, will determine the degree of caution required by public health bodies in terms of which threshold to aim for in a population. Albeit, vitamin D genetics only contribute around 7.5% to determining 25(OH)D concentration [53], so this is likely to only be a small consideration.

## 5. Other issues surrounding definition of thresholds for vitamin D

Tissues themselves, and by extension, organs, may have differing requirements for 25(OH)D, as well as for the active hormone (1,25-dihydroxyvitamin D; 1,25(OH)<sub>2</sub>D). This is likely part of the explanation for 25 nmol/L as a minimum threshold to ensure musculoskeletal health, but 50 nmol/L to ensure health for other tissues that has been demonstrated by evidence reviewed in this chapter (e.g., immune function, anti-cancer properties).

Country-based differences in population characteristics, and statistical approach used, as well as practicalities in terms of achieving threshold (diet, supplements, fortification, sunlight) also influence the setting of thresholds. Public health bodies may differ in their willingness to proscribe what is required to meet certain thresholds, based on how feasible the threshold is in terms of required dietary intake, or sunlight exposure that is realistic.

Finally, the assessment of vitamin D status is usually by assessment of serum or plasma 25(OH)D. The active hormone (1,25(OH)<sub>2</sub>D) is less often used in research compared with 25(OH)D as 1,25(OH)<sub>2</sub>D is tightly regulated physiologically and so may be normal even when bodily stores of vitamin D may be deficient. Threshold definitions, as described before, rely heavily on the concentrations of 25(OH)D required for health. However, it is unclear to what extent serum or plasma 25(OH)D is representative of vitamin D level in the whole body (e.g., in other tissue fluids, and in the tissue itself).

## 6. Conclusion

Recommendations for 25(OH)D thresholds have been commonly set at 25 nmol/L or 50 nmol/L, with the UK SACN setting 25 nmol/L, and the US/Canadian IOM,

EFSA, and the Nordic Guidelines setting 50 nmol/L. The variation stems from differences in the criteria used to establish the threshold, factors specific to the populations linked to the guidelines, and differing interpretations of available evidence. It is important to note that some population groups are likely to have more difficulty in achieving these thresholds, including darker skinned ethnic minority groups, older people (particularly those who are frailer, or in nursing homes), and those with certain health conditions or who are on medications affected by vitamin D metabolism. These groups may need assistance in terms of reaching relevant 25(OH)D thresholds. Furthermore, there are general issues with the concept of defining 25(OH)D thresholds at all; considering 25(OH)D does not necessarily reflect tissue vitamin D content, there are issues with feasibility influencing decisions about threshold setting, and tissues may differ in their requirements for vitamin D.

## 7. Summary points

- The UK SACN currently recommends 25 nmol/L as a cut-off for 25(OH)D sufficiency, based on ensuring musculoskeletal health only.
- The US IOM, EFSA, and the Nordic Guidelines currently recommend 50 nmol/L for 25(OH)D sufficiency, for ensuring musculoskeletal health (IOM, EFSA, Nordic), pregnancy (EFSA, Nordic only)-related health, and a variety of other nonmusculoskeletal outcomes (Nordic only).
- Some population subgroups may need extra support to meet these recommended 25(OH)D thresholds.
- There are issues surrounding the definition of thresholds including varying needs for 25(OH)D and 1,25(OH)<sub>2</sub>D in different tissue types, differences between the procedures for setting guidelines between public health bodies, and issues in using serum or plasma 25(OH)D to assess actual tissue requirements for 25(OH)D.

## Defining thresholds for vitamin D II

*Reinhold Vieth*

Department of Nutritional Sciences, Department of Laboratory Medicine and Pathobiology, Faculty of Medicine,  
University of Toronto, Toronto, ON, Canada

### OBJECTIVES

- Explain why everyone should want their serum 25(OH)D to be at least 30 ng/mL (75 nmol/L).
- Define “threshold” for vitamin D nutrition and why policy-makers misuse the concept of “evidence-based medicine.”
- Summarize the origin of current dietary guidelines for vitamin D.
- Review basic biology in the context of sunshine and vitamin D.
- Why it is impossible for nutrition clinical trials to match the quality of evidence achievable with and demanded of drug clinical trials.
- Summarize recent evidence in the context of cancer, mortality rates, multiple sclerosis risk, and life expectancy.
- The problem of COVID-19 and decisions about the role of vitamin D when there is not enough time for perfect information.
- Allay concerns about vitamin D toxicity.

### 1. Introduction

The dietary recommendation for any nutrient is based on the thinking that a “threshold” exists for the nutrient’s intake, beyond which further consumption of the nutrient delivers no additional benefit. But instead of benefit, the logic is that further consumption creates only progressively greater risk of harm [1] (Fig. 52.1).

The concept of a nutrient threshold is a trivialization that probably arose from the thinking that vitamins are simply cofactors that are needed qualitatively, so that enzymes can function properly. The concept of a threshold differs substantially from the rigors of pharmacology, in which the effects of drugs are regarded as following log–dose–response curves to produce gradually increasing effects [3]. For vitamin D, there are many putative functions related to health, and this vitamin is itself metabolized in a finely regulated manner to generate a signaling molecule, calcitriol, or 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D). The question of a threshold becomes complex: what are the requirements for the precursor, vitamin D, in the context of the multiple biological effects of its hormone, which include effects on bone and mineral health, cancer, immune function, mental health, etc. Furthermore, is the dosage threshold for vitamin D related only to the oral intake of the nutrient, or is the threshold related to a level of serum 25-hydroxyvitamin D (25(OH)D) the biochemical marker for vitamin D nutrition? To complicate these questions, what interactions are there in terms of changes in seasons of the year, sunshine, latitude, clothing, skin color, and cultural behavior?

The history of the fat-soluble vitamins extends back hundreds of years, to the time when a daily teaspoonful of cod liver oil was used in Scandinavia to help infants thrive [4,5]. The vitamin D content of that teaspoonful eventually became the basis for dietary guidance for vitamin D. A century ago, there were no dose-finding studies in clinical nutrition, and decisions were made empirically. Once it was realized that vitamin D was necessary beyond infancy to prevent osteoporosis, the use of the roughly 400 IU per day of vitamin D in a teaspoon of cod-liver oil became common throughout

**FIGURE 52.1** Summary and terminology of guidance values as they apply to vitamin D. [2], as paraphrased and interpreted by the author (RV) [1]. EAR, estimated average requirement, the intake that would satisfy the requirement for preventing the index condition (rickets or osteomalacia) for half the population, or for the average member of the population. RDA, recommended dietary allowance, the intake that would satisfy that requirement for 97.5% of the population. UL, the upper level, the long-term daily intake, beyond which the general public is advised to avoid. UF, an uncertainty factor, or margin of safety that keeps the UL well below the highest daily intake that has not been associated with harm. NOAEL, the no observed adverse event level, a daily average intake level that has not been associated with the specified measure of harm (hypercalcemia). LOAEL, the lowest observed adverse event level, an intake at which there is a clear risk of harm, in particular hypercalcemia. The specific values shown are the pertinent daily intake values for adults, as specified in the most recent IOM report [2]. Copyright R Vieth.

the lifespan, both for fortification of a quart or liter milk and for the vitamin D in supplements.

In the 1990s, clinical trials that combined tricalcium phosphate (Ostram(R)) along with vitamin D<sub>3</sub>, and that were funded by MERCK KGaA, Darmstadt, Germany, showed that 800 international units daily of vitamin D reduced rates of fractures in healthy older adults [6,7]. The sponsor was primarily interested in the calcium aspect of the research, as Pierre Meunier, the senior author of those trials, told me. The choice of the 800 IU/day of vitamin D<sub>3</sub> was based, quite simply, on his arbitrary decision to try using double the usual, 400 IU/day dose.

The 800 IU/day of vitamin D dose was chosen by Meunier, and it has now become the recommended dietary allowance for vitamin D for all people older than 70 years [2]. Other similar studies in the elderly showed that while fractures were not prevented with 400 IU/day [8], the combination of calcium with vitamin D at 700 IU/day did prevent fractures [9]. For the prevention of fractures, it does appear that 800 IU/day is the threshold beyond which clinical trials have failed to demonstrate any further benefit from giving more vitamin D [10–12]. However, if instead of an intake of

vitamin D, the focus is on a threshold for bone health and fracture prevention, then it becomes clear that the desirable minimum concentration is 30 ng/mL (75 nmol/L) [13–16].

There does remain a lack of evidence as to whether more than the 400 IU/day intake for children, which was intended to prevent rickets or osteomalacia, has longer-lasting effects at preventing fractures throughout the lifespan. It is also important to know that there no level 1 evidence that the current 600 IU/day RDA for vitamin D actually does any good at all for adults younger than the age of retirement. To conduct the lifespan-long randomized clinical trial that policy-makers want to see would be very difficult to conduct. There are clues that early-life vitamin D nutrition should benefit health in the longer term. In Lebanon, healthy adolescent girls having mean 25(OH)D of 12 ng/mL (30 nmol/L—well below the 50 nmol/L target for dietary recommendations) showed improved bone response within 1 year [17,18]. Since bone mass reaches its peak soon after age 20 years [19], and if osteoporosis is a concern, then should we not be certain to address the simple, low-hanging preventive fruit, like vitamin D, to mitigate osteoporosis later in life? During the teenage years, is it realistic to expect double-blind, placebo-controlled clinical trial evidence to test whether ensuring serum 25(OH)D levels of at least 30 ng/mL (75 nmol/L) affect peak bone mineral density? Is it wise for any parent today, to choose to wait for such evidence before adopting the target level of 30 ng/mL (75 nmol/L) for their own children? If I could make the following wager, I would be happy to do so: If a survey were taken of the people who have written chapters in this book, not even the most vocal skeptics about vitamin D would feel comfortable with the knowledge that their children or grandchildren were growing up having serum 25(OH)D levels below 75 nmol/L (30 ng/mL).

The unavoidable confounder for vitamin D nutrition research is the fact that most people acquire most of their vitamin D through exposure of their skin to ultraviolet light. That biggest problem that complicates health advice to the public is that, according to the dermatology community, “there is no such thing as a safe tan” [20]. The American Dermatology Association website states that adults should avoid sunshine and that the general public should simply adhere to the “evidence-based advice” of the Institutes of Medicine (IOM). The latest IOM report on vitamin D makes it very clear that it assumes essentially no vitamin D input from ultraviolet exposure of the skin [2]. But then, the neither the IOM nor any other agency can provide any clinical evidence for the long-term serum 25(OH)D response to a daily dose of vitamin D in people who were never exposed to sunshine. Therefore, so far as officialdom in North

America and elsewhere is concerned, the threshold for vitamin D has been reached, without level 1 evidence, by anyone adhering to official dietary guidance. Based on Bouillon's excellent comparative analysis of nutritional guidelines for vitamin D [21], the highest intakes recommended by any of the guidance authorities is as follows:

- 400 International Units (IU) for infants/children 0–1 years
- 600 IU for children, teenagers and adults 1–70 years
- 800 IU for adults 71+ years

Bear in mind, that despite official denials, the reality of those recommendations above must unavoidably be in addition to the vitamin D acquired from exposure of people to sunshine. Incidentally, the country with the world's lowest recommendation for vitamin D (100 IU/day) is the Russian Federation [21].

Is it really credible that the debate should end here? Is it correct for health policy to state that humans do not require sun exposure, and that the threshold for optimal health is ensured with an oral intake of 800 IU (20 µg)—or less—of vitamin D?

Clifford Rosen, who coauthored the chapter opposing the higher vitamin D requirement chapter in the previous edition of this volume [10,15], has been quoted in the journal, *Science*, as saying, "Evidence does not matter to many people when it comes to vitamin D," he maintains: "It is a religion. People really believe this stuff works." [22]. Others agree with Rosen's perspective that there is no evidence of net benefit from anything beyond official dietary guidelines [23–26]. A recent editorial comment by Clifford and Rosen in a high-profile journal commented on the negative fracture-prevention findings for the VITAL randomized trial of 2000 IU/day vitamin D. They concluded "Adding those findings to previous reports from VITAL and other trials showing the lack of an effect for preventing numerous conditions suggests that providers should stop screening for 25-hydroxyvitamin D levels or recommending vitamin D supplements, and people should stop taking vitamin D supplements to prevent major diseases or extend life." [125]. I regard that conclusion as disingenuous, because Clifford and Rosen must have been well aware that the healthy volunteer participants of the VITAL trial had average baseline serum 25(OH)D levels that were already at 29.3 ng/ml, which is at the 80th percentile value of the American population [82]. Those unusually high background serum 25(OH)D levels certainly satisfied any expected fracture-prevention function of vitamin D, and revealed a healthy volunteer bias for the VITAL study. I will go into more detail on this later in the cancer section of this chapter.

For formal guidelines, it seems that only the ultimate level of evidence is acceptable. But David Sackett who

led the group that developed the modern concept of "evidence-based medicine" (EBM) has clarified what he means by EBM.

"Because the randomized trial, and especially the systematic review of several randomized trials, is so much more likely to inform us and so much less likely to mislead us, it has become the "gold standard" for judging whether a treatment does more good than harm. However, some questions about therapy do not require randomized trials (successful interventions for otherwise fatal conditions) or cannot wait for the trials to be conducted. And if no randomized trial has been carried out for our patient's predicament, we must follow the trail to the next best external evidence and work from there" [27].

Clearly, evidence based medicine involves far more than just double-blind placebo-controlled clinical trials. To that, I would add that those very same official guidelines that demand the highest available evidence are in themselves subjective, and they are biased in their outcome by interpretations of evidence that depend on the very selection of the individuals chosen to review those data. By way of example, I coauthored an editorial along with 14 well-known experts in the field, calling for the IOM to review dietary guidance for vitamin D [28]. It stands as a clear example of committee-selection bias that not a single one of those 14 authors who had advocated for a review of vitamin D ended up on the panel selected for the Institute of Medicine review [2]. It is well known, that if advocates for one side of a contentious issue are excluded from decision-making, then the outcome favors the opposite side of that issue, in this case, biasing the review process in favour of the status quo.

As a glaring consequence of that bias, I direct the reader to the IOM approach to the way the committee analyzed bone biopsy data from accident fatalities in Germany, along with their serum 25(OH)D levels [29]. The IOM committee determined from its analysis of bone biopsy data of Priemel et al. that 20 ng/mL (50 nmol/L) is osteomalacia prevention threshold for serum 25(OH)D [2]. However, coverage of the debate in both the journal, *Science* [22], and the journal, *Nature* [30], shows dissenting opinions of others. Amling, the senior author of the biopsy data, disagreed strongly with the IOM analysis of the data his research group produced. The published figures of Priemel et al. show with absolute clarity that the thresholds for minimal osteomalacia, based on the observed osteoid volume, osteoid surface, and osteoid thickness are all at 30 ng/mL (75 nmol/L) [29]. Anyone who doubts the inappropriateness of the 50 nmol/L (20 ng/mL) threshold that the IOM adopted for 25(OH)D needs to take a serious look at the Priemel paper [29].

Another important point of contention relates to the methods that were used to calculate vitamin D intake

that would be needed to ensure the RDA target level for serum 25(OH)D. To allay the criticism that the committee might not be accounting for subpopulations with dark skin or older persons in institutions, the IOM guidance assumed minimal sun exposure as a basis for its vitamin D recommendations. In other words, the intent was that adherence to the RDA intake advice for vitamin D should, by itself, ensure a minimum serum 25(OH)D of 20 ng/mL (50 nmol/L) [2]. But more rigorous analyses have shown that if the aim is for 97.5% of the population to have a 25(OH)D concentration that is at least 20 ng/mL (50 nmol/L), then the most conservative of those peer-reviewed analyses concludes the intake needs to be 43.6 mcg/day (1744 IU/day) [31]. Other intake calculations to ensure 20 ng/mL (50 nmol/L) were even higher than that [31–34]. The RDA for vitamin D is still 600 IU/day for most people, an intake recommendation that does not stand up to scrutiny.

## 2. Human biology

Any evidence-based analysis of what is optimal for vitamin D should start with the basic biology of our species [35]. The fundamental concept in evolutionary biology is that it is environment during evolution that

determines genotype, and from the resulting gene pool, environmental change then drives the fine selection to affect phenotype. Evolution involves natural selection in a manner that optimizes the species' biology to suit the environment in which the species arose. Our own species originated in the horn of Africa. Early *Homo sapiens* are logically described as nudists whose skin was of type 6, on the 6-point Fitzpatrick skin type scale of skin darkness. Our species was “designed” through evolution to inhabit the tropics. The changes that accompanied the millennia-long migrations of *H. sapiens* across the various global environments resulted in selection of characteristics that maximized their ability to produce viable offspring [36–38]. While there is some debate as to the exact geographic region where the genes for whiter European skin originated [39], selection for lighter skin with distance away from the equator happened independently in both hemispheres, indicating that lighter skin color was multifactorial and driven by the environment [40,41]. Our best estimate of what serum 25(OH)D level should be regarded as biologically “normal” for *H. sapiens* is provided by Luxwolda and Muskiet who studied groups living traditionally in tropical Africa [42,43]. Fig. 52.2 shows the assembled published Luxwolda data from Africa and from healthy students at the University of

**FIGURE 52.2** Boxplots showing serum 25(OH)D nmol/L levels in of people from different ancestries in Africa (latitude 0) and during February in Toronto (43N). All results here assayed with the same Diasorin method. The Africa values are from Luxwolda and Muskiet [42,43], and these show traditionally living Masai and urban-living Bantu. Since humans originated in Africa, the Masai results logically indicate serum 25(OH)D levels that are “normal” for the human species. Levels of 25(OH)D in urban Africans match those of White Canadians, i.e., of European ancestry. People of non-European ancestry who live in north Toronto [44] exhibit half as much again, as the Masai levels. The box at the bottom right highlights 25(OH)D values at or below 25 nmol/L (10 ng/mL), which are regarded as the criterion for a diagnosis that rickets or osteomalacia was caused by vitamin D deficiency. Copyright R Vieth.

Toronto [44]. The figure begs the question, “Which of those boxplots should be regarded as the best representation of the ‘normal range’ for serum 25(OH)D?” Was there a bias shown on the part of my own laboratory and others when we decided to consider as ‘normal,’ specifically the 25(OH)D results of those persons who were of European Ancestry and who were living outside the tropics?

We should allow ourselves to take the perspective of primate biology. It should be logical to ensure that *H. sapiens*, who are that hairless, tropical, Great Ape, should have serum 25(OH)D levels higher than 80 nmol/L (32 ng/mL), just like what is normal for all other primate species that we care for [45,46]—and just like the 25(OH)D levels of traditionally living in sub-Saharan Africa [42,43]. Ensuring physiologically normal levels of 25(OH)D should be the biologically normal and ethical thing to do [47]. Would any animal-care committee allow any researcher to knowingly keep “healthy” primates in cages so that their serum 25(OH)D levels are less than half of what they would be in the wild?

But instead of thinking about the natural biology of our species, we fixate on what, by modern, clinical laboratory methodology is best described as the “reference interval” for the assay of serum 25(OH)D. Laboratory reference intervals are conventionally defined by the mean plus or minus two standard deviations, i.e., the 95% central interval of the lab test distribution of the local reference group sampled by the laboratory [48,49]. However, serum 25(OH)D is more severely affected by environment and culture than anything else that we can measure in the bloodstream. This metabolite is not like any “normal” laboratory test. Exactly who should make up that “reference group” that defines the reference range for serum 25(OH)D? Basic human biology points to the results published by Luxwolda et al. [42,43] for context as to what should be considered “normal” (Fig. 52.3).

### 3. Nutrition clinical trials cannot match the quality of evidence achieved with drugs

The argument for the status quo in terms of vitamin D starts from the premise that official guidance for vitamin D intake is correct and that avoiding sunshine is the right thing to do. Denial of benefit, beyond official recommendations, for vitamin D and sunshine is the advantaged side of this debate. Any statistical analysis starts off with the default position that the null hypothesis is the correct conclusion. How can you be wrong when you can always sit back and contend that your intellectual standard demands ever more evidence before you can be convinced?

**FIGURE 52.3** Evolutionary perspective of circulating vitamin D nutritional status. Boxes show median and quartile values for 25(OH)D of the primate groups that are represented by the cartoon above. Data are assembled from multiple sources that used the same DiaSorin assay method [5,43–45,50]. Copyright R Vieth.

If only the highest tip of the evidence pyramid will do, then we may as well forget about nutrition altogether. In the context of the role of any nutrient or dietary supplement in the primary prevention of disease, the expectation for the sort of evidence demanded is very high: You need multiple clinical trials that involve a healthy cohort, randomized to a supplementary intake of the nutrient in question. A clinical trial requires an a priori hypothesis that is specified for all to see, at a clinical trials registry such as [www.clinicaltrials.gov](http://www.clinicaltrials.gov). That hypothesis normally specifies that those people who are randomly and blindly assigned to the supplement will end up with fewer of the prespecified disease events than the placebo group.

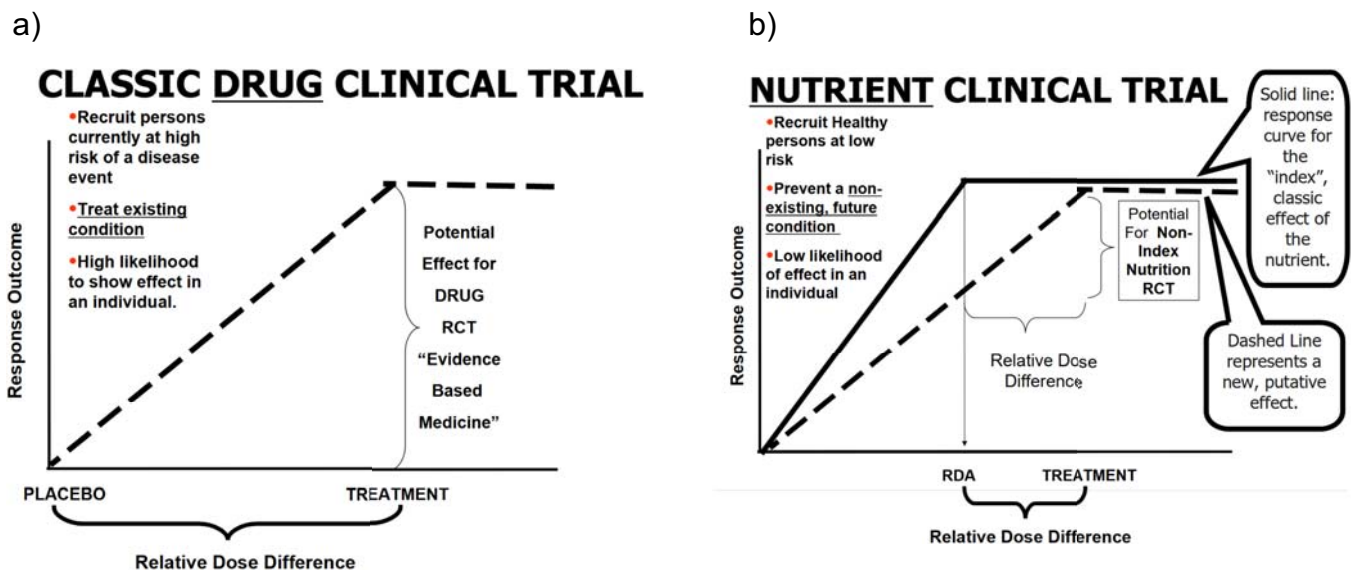

Very few nutrients suit the short-term contexts that can be conducted realistically for clinical trials. One rare exception is supplementation with higher intakes of folic acid, which has been shown to produce fewer occurrences of stroke [51,52]. But the largest of those clinical trials were conducted in China, without America’s folate-fortified flour [53], or they were conducted in subjects with high blood pressure who were already at greater risk of stroke [54,55]. Those shortcomings make the folate clinical trials not quite applicable for all populations. That aspect of research done on a subpopulation is analogous to the way the fracture prevention trials of vitamin D were conducted in the elderly, a particularly susceptible subgroup for fracture outcomes. But for folate, the evidence that a higher intake prevents stroke has not translated to an increase in official dietary recommendations.

“Primary prevention” is the prevention of disease events in healthy persons. “Secondary prevention” is the prevention of further disease events in persons already at greater risk or who were previously affected by the disease. Reviews for the US Preventive Services Task Force have specifically sought out primary-prevention studies of vitamins A, B1, B2, B6, B12, C, D, and E; calcium; iron; zinc; magnesium; niacin; folic acid; carotene; and selenium. The purpose was to review evidence for the benefit and harms of vitamin and mineral supplements in community-dwelling, nutrient-sufficient adults for the primary prevention of cardiovascular disease (CVD) and cancer [56–58]. With the exception of identifying paradoxical harms from beta-carotene and vitamin A with increased all-cause mortality, cardiovascular disease mortality, and lung cancer, the evaluations repeatedly came to the same conclusion that there was insufficient evidence to conclude any benefit or harm of any of the vitamins and minerals for the outcome events of total mortality, cancer, or cardiovascular disease. No nutrient is supported by causal, level 1 evidence for primary disease prevention in healthy adults. “Healthy,” of course meaning that the nutritional status of the study population, is already satisfied in the context of the index condition for each nutrient. (“Index condition” is the classic disease associated with deficiency of the nutrient). Even though these metaanalyses involve vitamin D intakes that range from 400 to 4000 IU per day, they pool vitamin D intake as if it is a binary, yes-or-no thing. The final presentation of the analysis – whether it is vitamin D or any other nutrient – is always that further increasing intake of the nutrient will not

deliver further benefit for the primary prevention of mortality, cancer, or cardiovascular disease.

Most nutrients are thought to exhibit a dose response that reveals threshold intake requirement, whereby the classic deficiency-disease condition for the nutrient is fully prevented at the oral intake typically defined as a recommended dietary intake (RDA) for the nutrient (Fig. 52.1) [2]. Policy-makers assume that intakes beyond that threshold do not provide further benefit, but only raise risk of harm [2,59]. That assumption poses a challenge to prospective clinical-nutrition researchers who are even thinking about conducting research into higher intakes. As innocent as the logic for risk mitigation might appear, it very much hinders the ability to obtain ethics committee approval for research aiming to look into vitamin D intakes higher than the stated upper level (UL) for the nutrient. Recommended nutrition policy becomes like a self-fulfilling prophecy, with research ethics review panels pushing new research in the direction that supports existing recommendations.

In a review addressing the challenges related to evidence-based nutrition, Blumberg et al. pointed out that classic, evidence-based medicine is based on a pharmaceutical model, and that “The level of confidence needed in defining nutrient requirements or dietary recommendations to prevent disease can be different from that needed to make recommendations to treat disease” [60]. Based largely on Heaney’s guidance for the design of nutrient clinical trials [61], Fig. 52.4 shows a comparison between the challenges to obtaining level 1, causal evidence with pharmaceutical clinical trials, versus nutrition clinical trials.

**FIGURE 52.4** Characteristics of clinical trial designs intended to demonstrate therapeutic efficacy of drugs (panel A). Features that pose particular challenges to the design and conduct of primary prevention clinical trial designs for nutrients (panel B). Copyright R Vieth.

The defense for policy-makers is logical: nutrient recommendations require higher confidence than pharmaceutical validation, because nutrient guidance applies to the entire population, and to intakes throughout the lifespan, to prevent (i.e., lower the risk of) primary disease. In contrast, pharmaceuticals are applicable to secondary intervention, that is, once disease exists. The risk/benefit profiles for vitamin D nutrition guidelines are vastly different for primary prevention, versus secondary prevention of disease events.

What further complicates nutritional, primary-prevention-of-disease research is the reality that development of new disease events may take more than the 5-year maximum time frame that is within the realm of what granting agencies are capable of supporting [62]. Table 52.1 lists currently known large randomized trials related to vitamin D. No clinical trials have or will continue with randomized, active-versus-placebo intervention beyond 5 years. However, measurable reductions of disease risk among healthy subjects will almost certainly require longer than that.

“Because the intakes required to prevent many of the long-latency disorders are higher than those required to prevent the respective index diseases, recommendations based solely on preventing the index diseases are no longer biologically defensible” [63,64].

Nutrition-related disorders such as osteoporosis or cancer are obvious examples of long-latency disease consequences, requiring a decade or more to develop or to prevent. If the focus is on causal, level 1 evidence, then we will forever remain blind to the efficacy of any increase in nutrient consumption that is maintained for years.

#### 4. Cancer

It has long been apparent that either sunshine or the vitamin D derived from it can lower cancer mortality [65]. In 2014, a Cochrane systematic review assessed the effect of supplementary intake of vitamin D versus placebo for cancer mortality. Four RCTs involved a total of 44,492 participants [66] with the conclusion was that vitamin D supplementation corresponded to a significantly lower relative risk (RR) for cancer mortality 0.88 (95% CI 0.78–0.98). The mean daily dose of vitamin D was 1146 IU (compared with no supplementation), and the mean length of follow-up was 6.3 years. Since not everyone considered the data convincing, the results of the VITAL study, with its 25,000 participants, were awaited through most of the past decade.

In 2019, the analysis of the VITAL study for the pre-specified primary outcomes was published [67]. The primary outcome of the VITAL study was the “prevention of occurrence of invasive cancer of any type,” and for

that result, the VITAL was not statistically significant [67]. Consequently, Bouillon contends that “No effects of vitamin D supplementation on cancer risk were observed in the large VITAL and ViDA trials” [25]. Likewise, a high-profile editorial by Keaney and Rosen closes cynically with, “Thus, in the absence of additional compelling data, it is prudent to conclude that the strategy of dietary supplementation with either n–3 fatty acids or vitamin D as protection against cardiovascular events or cancer suffers from deteriorating VITAL signs” [68].

The analysis of the VITAL study data regarding an effect of vitamin D did show a lower incidence of advanced (metastatic or fatal) cancer. But that only became clear for the data beyond the 1-year point into the trial [69]. It is important to bear in mind the background population for the VITAL study. The best data regarding general population of the United States is represented by the National Health and Nutrition Examination Survey (NHANES) sample, whose subjects were tested between 2001 and 2006, shortly before the start of VITAL clinical trial. In that NHANES assessment, only 19% of participants had 25(OH)D values  $\geq$  30 ng/mL. That context makes it very likely that the VITAL study, with its relatively high mean baseline 25(OH)D level of 29.3 ng/mL [70], was at least partly affected by a “healthy volunteer selection bias,” similar to what has affected other vitamin D studies [71].

The mean 25(OH)D concentration at baseline of participants in the VITAL study was already at the threshold for a vitamin D nutrition optimum that the Endocrine Society has long advocated [16]. Importantly, the VITAL study participants who were randomized to 2000 IU/day of vitamin D<sub>3</sub> had an average serum 25(OH)D concentration at year 1 that was 40.3 ng/mL (101 nmol/L) [70]. Two points warrant mention here. Firstly, if 2000 IU/day of vitamin D<sub>3</sub> raised the serum 25(OH)D by 11 ng/mL, then how much background vitamin D input must there have been due to sunshine, diet, and supplements in the study subjects to produce their baseline concentration of 29.3 ng/mL? Surely, that baseline supply of the nutrient was already far in excess of any dietary guideline of 800 IU/day or less. Secondly, if development of advanced cancer or cancer mortality over the next 5 years, in healthy adults, is a meaningful objective, then surely, the prevention threshold level for serum 25(OH)D must be at least the 40.3 ng/mL (101 nmol/L). One should also consider that the interquartile range on top of that was 10.4 ng/mL. That totals to 50.7 ng/mL as a reasonable cancer-preventive level for serum 25(OH)D, based on the 75th percentile level of the treatment arm [70].

The VITAL clinical trial needs to be considered as part of a metaanalysis. Similar clinical trials using vitamin D at 2000 IU/day were reported by Lappe et al. albeit in

**TABLE 52.1** Baseline and follow-up 25(OH)D concentrations and vitamin D dosing regimens of selected recent large vitamin D RCTs.

Study acronym or first author	Study population	Baseline 25(OH)D in the entire cohort (ng/mL)	Baseline 25(OH)D in the placebo group (ng/mL)	Follow-up 25(OH)D in the placebo group (ng/mL)	Baseline 25(OH)D in the vitamin D group (ng/mL)	Follow-up 25(OH)D in the vitamin D group (ng/mL)	Vitamin D supplement dose	Study follow-up duration
<b>VITAL</b>	Older general population	30.8 ± 10.0	30.8 ± 10.0	−0.7 from baseline	30.9 ± 10.0	41.8 (mean)	2000 IU per day	5.3 years (median)
<b>ViDA</b>	Older general population	25.3 ± 9.5	24.4 ± 9.6	26.4 ± 11.6	24.4 ± 9.6	54.1 ± 16.0	Initial 200,000 IU, followed by 100,000 IU per month	3.3 years (median)
<b>DO-HEALTH</b>	Older general population	22.4 ± 8.4	22.4 ± 8.5	24.4 (mean)	22.4 ± 8.4	37.6 (mean)	2000 IU per day	2.99 years (median)
<b>D2d</b>	Patients with prediabetes	28.0 ± 10.2	28.2 ± 10.1	28.8 (mean)	27.7 ± 10.2	54.3 (mean)	4000 IU per day	2.5 years (median)

conjunction with calcium supplement [72,73]. Recent metaanalyses have consistently come to the unambiguous conclusion that although vitamin D supplementation does not affect total cancer incidence, the analyses do unambiguously show that mortality from cancer is lower in the vitamin D-supplemented arms of clinical trials [74–76].

The evidence-based conclusion of benefit from double-blind, placebo-controlled clinical trials of vitamin D<sub>3</sub> is based on the binary, yes-or-no conclusion of statistical significance. To turn that binary knowledge into practice requires a statement of how much vitamin D supplementation is needed. The thing that is probably more important, is what serum 25(OH)D level should people aim for? It is logical to conclude conservatively from the efficacy demonstrated in the VITAL study that sustaining serum 25(OH)D at the 25th percentile of the treatment arm—i.e., 30 ng/mL (75 nmol/L) is a prudent preventive threshold level for healthy adults. Consistent with that value is a cross-sectional analysis of 25(OH)D data from one clinical trial [72] combined with data and a group of self-reported cohort referred to as Grassroots Health [77].

## 5. Mortality

Mortality is the least ambiguous outcome of all. Prospective epidemiological data suggest a protective association of higher serum 25(OH)D levels. Stated more correctly, the data consistently show higher mortality among those classified into the lowest group for serum 25(OH)D. Schottker et al. conducted a metaanalysis of eight prospective cohort studies from sample populations from Europe and the United States. The analysis was done by assembling the data on all the 6685 individual participants of the studies and classifying them into country quintiles of serum 25(OH)D. Mortality was consistently highest for those in the lowest 25(OH)D quartile. The relationship did not differ across countries, sexes, seasons of blood draw, or age groups [78]. Despite differences in mean serum 25(OH)D among reported studies, Schottker et al. observed that it was always the lowest quantile that showed highest mortality, making it difficult to define a threshold serum 25(OH)D for lower mortality [78]. However, there are suggestions of higher mortality for higher serum 25(OH)D quintiles; for example, the Newcastle 85+ Study showed a U-shaped higher mortality relationship [79]. But for the latter cohort, the higher mortality in those at the highest category of serum 25(OH)D was no longer significant after statistical adjustment for mental health and morbidity-related variables. That suggests a “confounding by indication” bias, whereby vitamin supplementation is higher because of known risk of, or presence of,

disease. A similar analysis has been reported for the Chinese Longitudinal Health and Longevity Study (CLHLS). In that study, Mao et al. looked at plasma 25(OH)D levels in 2185 Chinese adults older than 79 years (mean 93 years) [80]. There, all-cause mortality decreased progressively with rising plasma 25(OH)D, with the lowest mortality in those with 25(OH)D at or higher than 75 nmol/L (30 ng/mL). Among 3408 NHANESIII participants, older than 64 years and prospectively followed up for a median of 7.3 years, all-cause mortality was highest in those with baseline 25(OH)D levels less than 50.0 nmol/L, but the authors concluded that levels of at least 100.0 nmol/L may be necessary for better survival [81]. One problem with the available epidemiological data is that very few people have 25(OH)D higher than 75 nmol/L. Sparse numbers of data points result in wide confidence intervals, to the point that some, such as the IOM, interpret the uncertainty of wide confidence bands as indicative of greater risk at higher ranges of 25(OH)D levels [2]. Lastly, Ford analyzed data from 7531 participants in an NHANES cohort in the United States further and reported the fully adjusted HR per 10 nmol/L of vitamin D was 0.93 (95% CI: 0.86–1.01) [82]. I mention the NHANES data here because these epidemiological survey results on mortality are consistent with the metaanalysis of randomized clinical trials reported by Autier and Gandini, as described in the next paragraph.

The key questions remain, “Is mortality lower in healthy subjects who are randomized to higher intake of vitamin D versus placebo? And if so, what is the optimal daily intake recommendation?” The first to address these questions were Autier and Gandini, whose metaanalysis consisted of 18 independent randomized controlled trials, involving 57,311 participants [83]. The doses used in the clinical trials conducted up to the year 2006 ranged from 300 to 2000 IU/day (all were vitamin D<sub>3</sub>). For the pooled vitamin D arm of those trials, the relative risk for mortality from any cause was 0.93 (95% confidence, 0.87–0.99), versus placebo, regardless of whether these osteoporosis clinical trials included calcium supplements. The findings of the Autier and Gandini metaanalysis were confirmed in the report done for the Cochrane Collaboration and authored by Bjelakovic et al. [66]. Several interesting conclusions were drawn by Bjelakovic et al. The clinical trials involving vitamin D<sub>2</sub>, alfalcidol, or calcitriol had no significant effect on mortality [66]. The lack of success in clinical trials using vitamin D<sub>2</sub> should not come as a surprise to anyone who has compared the characteristics of vitamin D<sub>2</sub> versus vitamin D<sub>3</sub> [84–86]. The more recent metaanalysis by Zhang et al. included data from long-awaited, large randomized clinical trials, and there, the conclusion was that vitamin D supplementation alone was not associated with all-cause mortality in

adults compared with placebo or no treatment [74]. What makes the recent, large clinical trials relevant is that subjects were younger and healthier than the subjects were in the osteoporosis-focused trials done earlier. Hence, with the healthy subjects, event rates for death as a proportion of the sample were lower, biasing the results toward a null outcome for overall mortality. Nonetheless, despite no effect on mortality from cardiovascular disease, cerebrovascular disease, or ischemic heart disease, Zhang et al. found that vitamin D supplementation lowered cancer mortality by 16% (95% CI 0.74–0.95) [74].

A comment is warranted regarding the conduct of large clinical trials and the dosage interval. The challenge for anyone designing the trial is, how can one ensure long-term compliance to the protocol of a double-blind, randomized clinical trial in healthy people who, individually, will almost certainly not be able to detect any benefit from taking part? There are three obvious solutions: have salaried research staff regularly engage with study subjects as a means of keeping participants motivated; maximize sample size to overcome confounding factors, dropouts, or imperfections; and lastly, simplify the task of taking the study drug/nutrient to minimize the effort for participants. A longer dosing interval is a well-recognized method of improving compliance, not just for pharmaceuticals but also for vitamin D [87]. The first two approaches make the research too expensive for most granting agencies to fund. The last option, to simplify the ordeal of taking the drug/nutrient, is the easiest approach. However, clinical trials in which vitamin D is taken at intervals of weeks or months [11,88,89] or even a bolus dose of vitamin D annually have usually achieved null, or even adverse effects [90]. Nonetheless, metaanalyses generally combine all data from all available clinical trials, regardless of dosing protocol [2].

It is not enough to deliver a “threshold” level for serum 25(OH)D. Unlike other vitamins, vitamin D is not a metabolic cofactor. Cholesterol, the precursor substrate for steroid hormones, circulates and is available in millimol-per-liter concentrations. Like cholesterol, vitamin D is the structural precursor for a steroid-like hormone. But unlike cholesterol, the vitamin D and 25(OH)D are available to the body in miniscule, nanomolar concentrations; that is, vitamin D metabolite concentrations are six orders of magnitude less than cholesterol, the paradigm for how the rest of endocrinology functions! The point here is that nanomolar concentrations of enzyme substrate add unique complexity to the way the synthesis and breakdown of the hormone, 1,25(OH)<sub>2</sub>D, are regulated. The enzymes of the vitamin D system function under the unusual circumstance of first-order reaction kinetics. Yield of product is determined not just by the amounts of the hydroxylase enzymes but also by substrate concentrations as well

[91]. It takes time for the vitamin D system to adjust to nonphysiological, sudden, bolus doses of vitamin D [92,93]. Since vitamin D is normally acquired gradually through long-term exposure of skin to sunshine, acute bolus doses of vitamin D are not physiological. The dosage interval for vitamin D, taken either as a drug or a supplement, has long been a personal interest of mine. It is particularly upsetting that despite warning against long dosing intervals for vitamin D in 2009 [92], subsequent clinical trials used them, and those negative clinical outcomes have been assimilated into metaanalyses along with trials that used daily dosing. Distinctions to be considered in metaanalyses must include the form of vitamin D, the daily equivalent dosage, and the dosage interval [94].

## 6. Cardiovascular

Nutrients reputed to lower risk of cardiovascular disease include fish oils, antioxidants, selenium, and vitamin D. Much of the basis for having undertaken those studies lies in epidemiology and theory.

Metaanalysis of clinical trials has been highly convincing for the null hypothesis that vitamin D supplementation at various doses has not lived up to the expectation of cardiovascular benefit [51,95]. But then, how can one explain the cross-sectional data pertaining to serum 25(OH)D and cardiovascular health [81,96]? Autier et al. contend that the survival benefits related to higher serum 25(OH)D are secondary to other factors such as diseases that may keep people less active and indoors, as well as lifestyle. They conclude that “associations between 25(OH)D and health disorders reported by investigators of observational studies are not causal” [97].

However, Mendelian randomization analyses do point to a causal connection between serum 25(OH)D and cardiovascular disease risk [98,99]. It is just that the dose response for the outcome of cardiovascular benefit with vitamin D is satisfied once serum 25(OH)D reaches 20 ng/mL (50 nmol/L). In other words, most clinical trials of vitamin D probably resulted in a negative, null-hypothesis result, because they started with a serum 25(OH)D that was already high enough to minimize its role in cardiovascular disease risk. Not all outcomes for vitamin D nutrition need to exhibit the same dose–response curve.

What must not be overlooked in terms of cardiovascular health are the effects that sunlight on the skin per se has on the cardiovascular system, as presented by Liu et al.: Firstly, sunshine warms the skin, which causes vasodilatation and lower blood pressure. Secondly, the skin is a production and storage location for nitric oxide, a potent vasodilator, and which is released into the general circulation when skin is

exposed to sunshine. Thirdly, UVA, corresponding to natural sunlight exposure for 30 min at noon on a sunny day at 41 degrees north latitude, vasodilates the arterial vasculature in a way that is independent of nitric oxide synthase or skin temperature [100]. This complex of mechanisms prompted Liu et al. to conclude “We are concerned that well-meaning advice to reduce the comparatively low numbers of deaths from skin cancer may inadvertently increase the risk of death from far higher prevalent CVD and stroke, and goes against epidemiological data showing that sunlight exposure reduces all-cause and cardiovascular mortality [101].” The cardiovascular and mortality relationships with skin cancer are consistent with the work of Lindqvist et al. who surveyed Swedish women about sun avoidance. Lindqvist et al. showed that women who minimized their exposure to sunshine exhibited rates of cancer and overall mortality that were comparable to effect of smoking cigarettes [102].

## 7. Toxicity

Warnings about higher intakes of vitamin D [25,103] are often disingenuous in their repeated referencing to tolerable upper limitations based on the IOM discussion of risks with vitamin D [2], and where that IOM discussion focused in particular, on the clinical trial of Sanders et al. [90]. That is, despite multiple references to toxicity, objections to higher intakes to vitamin D were all fixated on the same publication, namely Sanders et al. a clinical trial published in a high-profile journal, but in which vitamin D was given as an annual bolus dose. It should not come as a surprise to anyone, if there is harm associated with the once-yearly administration of any nutrient. Nonetheless, the observation of increased rates of falls after the once-a-year administration of vitamin D seems to be taken as a suitable thing to use as basis for a generalization about the risks of vitamin D. I contend that the repeated citing of Sanders et al. in the context of vitamin D safety by the IOM and others [2,103] is done because this report is a convenient way to help convince an uncritical readership about the risks of vitamin D. Years ago, I investigated the basis for statements about vitamin D toxicity in the context of what might be pertinent to dietary guidelines and was surprised that I could not track any of the statements down to the actual published evidence [5]. Hypercalcaemia is the index of vitamin D toxicity, and for that, the field has not changed. However, the more recently characterized feature pertinent to adverse effects with vitamin D relates to the intermittent, bolus dosing described elsewhere in this chapter [92–94].

Concern about toxicity of vitamin D that is consumed at 4000 IU/day becomes moot if one considers that this

is within the amount of vitamin D produced naturally from sunshine. That is, the resulting level of serum 25(OH)D, exceeding 30 ng/mL (75 nmol/L), is physiological and normal for the humans [42,43]. Moreover, 48 weeks of vitamin D<sub>3</sub> taken at 14,000 IU daily was safe in a randomized clinical trial patients with multiple sclerosis [104–106]. I mention the multiple sclerosis clinical trials to confirm that the no observed adverse effect level (NOAEL) for vitamin D<sub>3</sub> consumption ranges of up to 10,000 IU/day as specified in earlier reviews and including by the IOM [2,5,107]. The application of a safety margin to that NOAEL results in the “tolerable upper intake level” (UL) that specified by the IOM as 4000 IU/day. I am not advocating vitamin D intakes beyond 4000 IU/day, but rather, restating here some of the known evidence of a wide margin of safety for vitamin D.

## 8. Multiple sclerosis

Chapters 101 and 102 of this book focus on the role of vitamin D in multiple sclerosis, which is an acquired autoimmune disease. For consideration as to a desirable threshold for serum 25(OH)D in children in terms of risk for multiple sclerosis, consider results published by Banwell et al. [108]. Briefly, serum 25(OH)D levels were measured in 302 children at the time when they presented with incident central nervous system demyelination syndrome (usually an isolated, acute phenomenon) at healthcare facilities across Canada. Whether or not those children progressed toward a diagnosis of multiple sclerosis was assessed after a mean follow-up of 3.2 years after presentation. In multivariable models, independent predictors of the eventual development of multiple sclerosis were HLA-DRB1\*15 alleles, remote Epstein–Barr virus infection, and low serum 25(OH)D. There were no interactions between the three predisposing factors. Risk of eventual diagnosis of multiple sclerosis was lowest in those children who, at the time of presentation, had serum 25(OH)D higher than 74 nmol/L (Fig. 52.5).

Is there any causal, level 1 evidence that children or adults who consume additional vitamin D will lower their risk of developing multiple sclerosis? Those who work in the field of Mendelian randomization regard the method as capable of demonstrating a “causal” connection. There are now many publications that used Mendelian randomization and that have sufficient statistical power to relate genetically estimated variations in serum 25(OH)D to risk of multiple sclerosis [99,109,110]. If there is compelling evidence for a causal connection between serum 25(OH)D concentration and risk of multiple sclerosis, the key question remains, exactly what can be done about it?

**FIGURE 52.5** Boxplots showing serum 25(OH)D levels measured on 302 children at the time they presented with acute demyelination syndrome and classified according to whether or not they were diagnosed with multiple sclerosis within the next 3.2 years of followup (panel A). Risk of subsequent diagnosis of multiple sclerosis for each quartile of those 25(OH)D values (panel B). These are graphical presentations of the data from the previously published study by Bantwell et al. [108]. Copyright R Vieth.

In December 2011, the National Multiple Sclerosis Society in the United States hosted a conference entitled “Vitamin D and MS Prevention International Workshop.” The MS Society invited statisticians, experts in clinical trials, multiple sclerosis, and nutrition from around the world to develop a plan. Despite intense discussion about what to do, or how to answer the key question about the role of vitamin D, now, over a decade later, nothing came of it. No registered clinical trial deals with the primary prevention of multiple sclerosis [111]. The reasons for this lack of progress are obvious if one thinks through an example of a power calculation that shows what would be needed for a suitable clinical trial (Fig. 52.6 boxes). It is not realistic to expect that any double-blind, randomized clinical trial will ever appear that overcomes the challenges of funding and conducting suitable primary disease prevention research that requires 1 million person-years of placebo-controlled intervention.

There is now relevant RCT evidence that vitamin D supplementation lowers the risk of the secondary outcome of all incident autoimmune diseases as confirmed by medical record review. Although multiple sclerosis was not included, the subjects in the VITAL study who were randomized to 2000 IU/day of vitamin D<sub>3</sub> were 22% less likely to be diagnosed with an autoimmune disease [112]. It is worth pointing out that same daily vitamin D<sub>3</sub> intake, 2000 IU/day, was the dosage that was the one most considered at the multiple sclerosis prevention conference mentioned in Fig. 52.6. Based on the perspective of Sackett [27], this is a

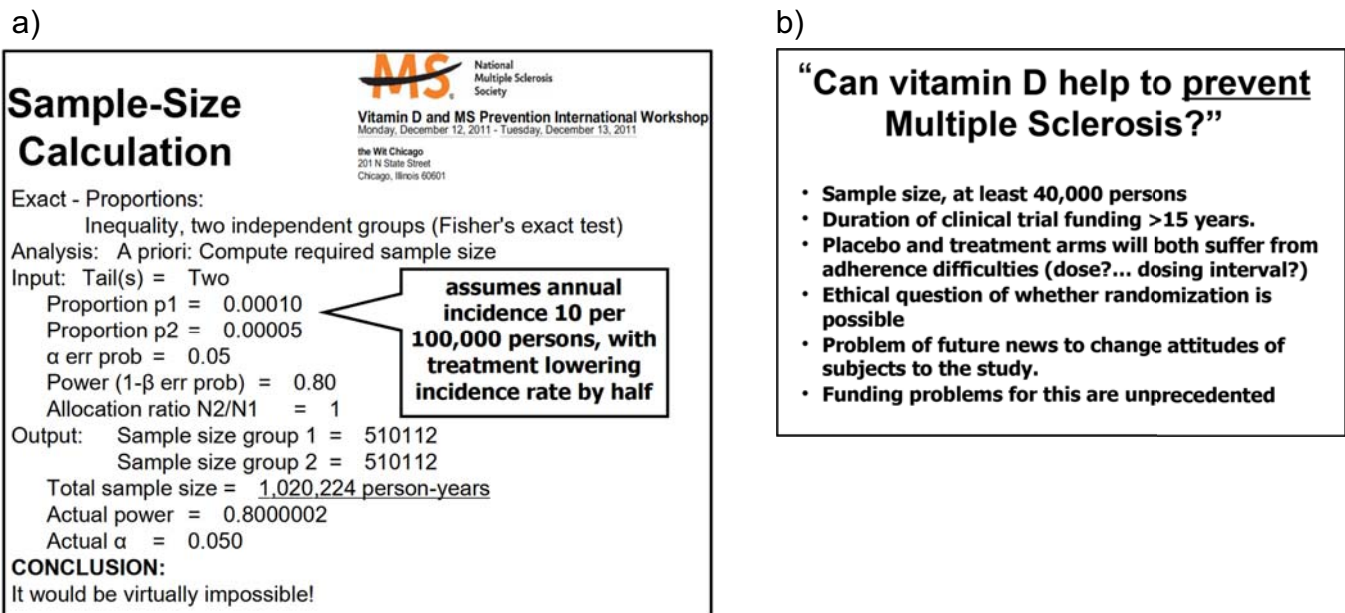

situation that requires advice that is based on the best available evidence, which in this case is something less than a double-blind RCT.

## 9. COVID-19

Before the era of COVID-19, observational studies consistently reported that lower serum 25(OH)D was associated with higher risk of upper and lower acute respiratory infections (ARIs). For example, among a nationally representative sample of 14,108 adults in the United States, who were asked at the time of testing, 4.8% reported having had an acute respiratory infection in the previous 30 days. After adjusting for season, demographic factors, and clinical data, having serum 25(OH)D below 30 ng/mL (<75 nmol/L) was associated with 58% higher odds of acute respiratory infection, and those rates of respiratory infection increased progressively with declining serum 25(OH)D concentrations [113].

Since early 2020, there have been many non-peer-reviewed preprints made available online in addition to properly accepted publications on the topic “COVID, vitamin D.” Manson and Bassuk cited several unpublished studies [114], but several of the more interesting reports that they summarized are no longer available to access, presumably because they were withdrawn, or they failed peer review. Complete knowledge on the topic of COVID-19 will take years. By the time the role of vitamin D in COVID-19 becomes clear, it may not matter any more.

**FIGURE 52.6** Power calculation arising from MS society workshop to address the question, “does vitamin D lower the risk of MS in healthy persons?” (panel A). The implications of that power calculation (panel B).

One of the earliest published reports relating serum 25(OH)D to COVID-19 infection was by Hastie et al. Their manuscript was submitted on April 19, 2020, within the first month of when most of the world was locked down. The manuscript was accepted for publication in record time, the very next day [115]. The investigators used UK Biobank data on 502,624 participants aged 37–73 years from across England, Scotland, and Wales. The serum 25(OH)D level had been measured at the time of recruitment, between the years 2006–2010. Median 25(OH)D had been lower in the Biobank participants who, at least 10 years later, in 2020, had a confirmed COVID-19 infection. In the infected subjects, the 25(OH)D median had been 28.7 nmol/L (IQR 10.0, 43.8) (i.e., median 11.5 ng/mL) compared with “other participants” who had had their median measured at 32.7 (IQR 10.0, 47.2) nmol/L (i.e., median 13.1 ng/mL). In other words, persons with confirmed COVID-19 infection had had significantly lower vitamin D nutritional status than those who were not infected ( $P < .01$ ). However, after statistical adjustment for 15 other variables that included predictors known to affect or be affected by vitamin D status, such as ethnicity, season, and health status, the 4 nmol/L (1.6 ng/mL) difference in serum 25(OH)D between COVID-19 infected versus “other participants” was no longer statistically significant. It is hardly worth asking the question, but should 4 nmol/L (1.6 ng/mL) really be expected to make any difference in people who, a decade prior, had such low 25(OH)D levels? The UK Biobank sample size of hundreds of thousands of people was very impressive. Less impressive was the assumption that a

decade-old result for 25(OH)D should affect risk for COVID-19 now. Comfort of a journal to accept a negative conclusion is evident, because after the authors adjusted for several factors that normally do correlate with serum 25(OH)D, there was no longer a statistical relationship. My point is that statistical nonsignificance was forced inappropriately. Adjustment for factors that are known to determine the independent variable in a relationship will of course neutralize the apparent effect of that variable (i.e., the authors neutralized the ability to detect any effect of the 25(OH)D level). The publication by Hastie et al. lacks evidence of a critical peer review. If there is a publication bias, it is that journals have a “bad news bias,” whereby acceptance of submissions favors negative results involving vitamin D over submissions offering “good news” results.

Another early publication was submitted in late April 2020, but that article showed a positive outcome, and it took longer to review. D’Avolio et al. addressed the question of whether serum 25(OH)D is lower in patients with PCR-confirmed COVID-19 infection compared with those who tested negative [116]. In their COVID-19-positive patients, serum 25(OH)D was (11.1 ng/mL; 27.8 nmol/L), significantly lower than in the comparable patients who tested negative (24.6 ng/mL; 61.5 nmol/L) ( $P = .004$ ). Subsequent similar work, such as that of Dror et al., shows that patients with vitamin D deficiency (defined as  $<20$  ng/mL) were 14 times more likely to have severe or critical disease than patients with 25(OH)D of at least 40 ng/mL (at least 100 nmol/L) (odds ratio [OR], 14; 95% confidence interval [CI], 4 to 51;  $P < .001$ ) [117]. Consider the context of serum

25(OH)D among these studies: Hastie et al. concluded no prognostic differences in serum 25(OH)D for COVID-19 positive patients versus other Biobank subjects, for whom all median values were well below 20 ng/mL (50 ng/mL) [115], while the reports that do show lower serum 25(OH)D concentrations in COVID-19 patients, all groups had levels well above 20 ng/mL (50 ng/mL) [116,117].

Research into COVID-19 has exploded dramatically, but the formal review process has been slow to respond. For example, a Cochrane collaboration produced a “living systematic review” that analyzed data up to March 2021 [118]. Even though the authors promised to update periodically, there is still no update two years later, at the time of this writing. Others, like the National Institutes of Health in the United States, updated their guidance in late 2022, after the severe part of the pandemic was over, and vaccinations were common [119]. Despite the slow and conservative approach of official guidance, some credible academics have been conducting an ongoing, real-time metaanalysis covering

vitamin D and COVID-19 [120]. The website to access their metaanalysis is <https://vdm-meta.com>. The contributors to [vdm-meta.com](https://vdm-meta.com) have chosen to remain anonymous to avoid the emotion, politics, and controversy that has surrounded the entire field of COVID-19. Although [vdm-meta.com](https://vdm-meta.com) is not peer reviewed in the normal sense, the rigor of data collection and level of descriptive analyses of the studies are credible. It merits the attention of anyone interested in any clinical aspect of vitamin D in the COVID-19 epidemic. Fig. 52.7 is an example of the ongoing metaanalysis. The publications cited for the metaanalysis shown in the figure are detailed at the website [120].

Among the challenges that are best described as unavoidable biases to elucidating whether taking more vitamin D can lower risk of undesirable aspects of COVID-19, such as risk of infection, or severity, or hospitalization or death are:

1. COVID-19 continues to evolve into multiple variants, causing changes to the nature of the disease itself, and its efficiency of transmission;

**FIGURE 52.7** Random effects metaanalysis of clinical trials of vitamin D for the outcome of preventing COVID-19 infection. This is an example of the ongoing analysis of vitamin D and COVID-19. Presented at [vdm-meta.com](https://vdm-meta.com) [120], accessed May 23, 2023; Reprinted with open-source permission.

2. human behavior, the wearing of masks and physical distancing change during the pandemic;
3. vaccination lowers incidence of the disease;
4. efficacy of vaccination varies, and it wanes with time.

For COVID-19, can there be any residue of benefit left to detect in a clinical trial of a nutrient like vitamin D? As an example of the ongoing challenges listed before, a preprint of a submitted manuscript shows a well-conducted clinical trial by Jolliffe et al. involving 3100 participants in the United Kingdom [121]. That vitamin D clinical trial shows no benefit from 6 months of 3200 IU vitamin D<sub>3</sub> daily (see Jolliffe, Fig. 52.7). The problem was that by 6.0 months into the clinical trial, to June 2021, 89.1% of participants had received one or more doses of a COVID-19 vaccine <https://www.medrxiv.org/content/10.1101/2022.03.22.22271707v1>). The impressive level of vaccination of the participants casts doubt on validity of this clinical trial and this clinical trial is another example of the “healthy volunteer bias,” which poses challenges that must not be ignored when assessing disease-prevention research for nutrition in general.

Clinical trials that are not confounded by the emergence of vaccines for COVID-19 are rare. However, in April 2022, Villasis-Keever et al. published a double-blind, placebo-controlled clinical trial that was conducted from July to December 2020 in hospital workers who were at high exposure to infected patients [122]. Of the 192 subjects completing the 45-day protocol, SARS-CoV-2 infection rate was lower in those randomized to 4000 IU/day vitamin D<sub>3</sub> than in the placebo-treated group. Infection rates were 6.4% versus

24.5%, respectively, ( $P < .001$ ) (see Villasis in the meta-analyses shown in Fig. 52.7). Baseline 25(OH)D was relatively low, at 18.3 (interquartile range 14.6,22.9) ng/mL (median 46 nmol/L), and the level increased by 8.8 ng/mL with treatment. The RCT published Villasis-Keever is a rare clinical trial that met the challenges of the time: it was conducted relatively early in the pandemic, it was not affected by vaccines, the study population was healthy but did exhibit the expected high rates of infection events because they were front-line medical workers. This study can be classified as “level 1 evidence” for a prophylactic effect with 4000 IU/day of vitamin D<sub>3</sub>.

As an example of opinion-based guidance, a petition published online of recommendations for vitamin D is listed at <https://vitamindforall.org/letter.html>. The page lists the daily personal intakes of many people knowledgeable about vitamin D (including some who are authors of chapters in this book). While not scientifically valid, the listing shows the personal conviction that comes with knowledge about the field of vitamin D. Manson and Bassuk closed their thoughtful “call to action” commentary about vitamin D and COVID-19 with the following words: “during the current pandemic, a supplement containing 1000–2000 IU/day of vitamin D would be reasonable” [114]. However, if one considers the serum 25(OH)D concentrations that accompanied the benefit observed in their VITAL clinical trial [70] and if one looks at the relationship of serum 25(OH)D in patients tested positive COVID-19 versus disease severity (Fig. 52.8), then it does seem rational to advise the public to sustain serum 25(OH)D at levels

**FIGURE 52.8** Severity of COVID-19 infection in relation to serum 25(OH)D measured within 2 years prior to the positive PCR test. Box-and-whisker plots of the most recent preinfection serum 25(OH)D levels ( $N = 253$ ). Shown are comparisons of median 25(OH)D levels between the four categories of COVID-19 disease severity as determined by the WHO definition (WHO/2019-nCoV/clinical/2020.5). Note that 75% (top three quartiles) of those classified with mild COVID19 had serum 25(OH)D that was at least 30 ng/mL (75 nmol/L). Reprinted with open-source permission from [117].

of at the very least 30 ng/mL (75 nmol/L) by whatever means available, be it from sun exposure, diet, or supplement. To ensure that almost all adults have serum 25(OH)D levels that exceed that minimum value requires an input of vitamin D<sub>3</sub> approaching 4000 IU/day for white adults [34]. For adults with dark skin who live at high latitudes, the intake would need to be substantially higher yet [123].

## 10. Conclusion

Evidence presented in chapters throughout this book reveals that vitamin D nutrition holds great potential benefits for health and disease. It is easy to remain skeptical of any benefit beyond current guidelines. The classic justification for skepticism about all biomedical research is exemplified by John Ioannidis, who is well known for his contention that “most published research findings are false” [124]. In contrast, a reading of Sackett [27], who details what evidence-based medicine is and what it is not, would be more appropriate when it comes to the debate about vitamin D. Evidence-based medicine leads to the conclusion that while most research is not perfect, imperfection is not a good reason to ignore the evidence that is at hand. Ignoring evidence for prevention of disease creates unnecessary risk for disease.

## 11. Summary points

- The biologically “normal” range for serum 25(OH)D is best represented by levels observed in traditionally living people in sub-Saharan Africa. Their serum 25(OH)D levels are at least 30 ng/mL (75 nmol/L) with median values of about 40 ng/mL (100 nmol/L).
- Dietary guidelines for vitamin D derive from the historical use of vitamin D in a teaspoon of cod-liver oil, and clinical trials of double that dose that succeeded in preventing fractures in older subgroups.
- Most of the evidence supporting a 25(OH)D threshold of 30 ng/mL (75 nmol/L) comes from prospective epidemiological data, not clinical trials.
- There is no nutrient for which clinical trials have shown level 1 evidence for primary disease prevention in adults younger than the age of retirement. Because it may be impossible to produce clinical trials in nutrition that match the quality standards of pharmaceutical trials, a standard of evidence that is less than “level 1” may be required.
- Vitamin D nutrition, whether from sun exposure, diet (including fortification), or supplementation, benefits musculoskeletal health, autoimmune disease (including multiple sclerosis), cancer mortality, as well as risk of COVID-19 infection, its severity and outcomes.
- To sustain a 30 ng/mL (75 ng/mL) threshold for serum 25(OH)D in 97.5% of the population requires a combined vitamin D<sub>3</sub> supply of 4000 IU/day via UVB exposure, diet, and/or supplement.

# Methods of evaluating population studies of vitamin D: strengths and weaknesses

*Edward Giovannucci*

Harvard TH Chan School of Public Health, Boston, MA, United States

## OBJECTIVES

- Summarize the main goals of population-based studies to our knowledge of vitamin D and health.
- Provide a conceptual framework of the various methods that can be used to assess vitamin D status in epidemiologic studies.
- Summarize the various methods used to assess vitamin D status, including epidemiologic studies, including circulating 25(OH)vitamin D, dietary and supplemental intake, sun exposure, predicted 25(OH) D, and genetic determinants.
- Describe the main challenges inherent in all epidemiologic studies of vitamin D and health.
- Summarize the main strengths and limitations of each of the major study types, including ecologic, cohort, case–control, interventional and Mendelian randomization studies.
- Understand the key issues in interpreting results from various study designs to inform on causal associations between vitamin D and health or disease outcomes.

## 1. Introduction

Population studies can be divided into two main types: observational and interventional (experimental). It is often stated or inferred that observational studies evaluate whether associations exist but cannot prove causality of the associations. Causality can only be

definitively established in interventional studies, typically a double-blinded randomized controlled trial (RCT). While this concept is true in principle, definitive RCTs are not always available or feasible, and even when available, RCTs have their own limitations. Issues related to RCTs are briefly addressed here, but several other chapters in this book will consider this type of study in more detail. Because of the long induction periods over which many diseases develop and progress, and the multifactorial nature of disease, typically no single approach can address all the potentially relevant shortcomings simultaneously. Thus, it is critical to understand the major strengths and limitations of all the approaches utilized to determine whether any association is likely to be causal.

Various types of epidemiologic study designs have been implemented to test the hypothesis that vitamin D is associated with numerous medical conditions and diseases. Meanwhile, only limited interventional data (RCTs) have been conducted for some of the disease end points of interest. This chapter will present an overview of the types of epidemiologic study designs utilized, and their strengths and limitations in addressing various hypotheses related to vitamin D. Relevant examples are given for illustration. This chapter focuses on methodologic issues in designing and interpreting epidemiologic studies and does not summarize in detail specific disease topics, which can be found elsewhere in the book. This chapter can serve as a basis for understanding the methodologic issues that may enhance understanding of these specific vitamin D–disease relationships.

This chapter will be divided into four sections. First, the various methods of assessing vitamin D status in

epidemiologic studies will be reviewed. Secondly, four key general issues in assessing validity of studies will be summarized. Thirdly, the major types of study designs that have been utilized will be reviewed, with major strengths and limitations to take into account. Finally, considerations when synthesizing an entire body of studies on a topic, as opposed to evaluating inference based on an individual study, will be provided in the conclusions.

## 2. Methods of assessing vitamin D status

### 2.1 Conceptual framework of assessing long-term vitamin D status

Vitamin D status can be influenced by diet (including supplements and fortification) and by solar or artificial ultraviolet-B (UV-B) light exposure. In addition, vitamin D status is affected by genetic factors and by endogenous factors, such as body mass. The multifactorial determinants of vitamin D status add challenges in designing epidemiologic studies and interpreting results. The gold standard to assess vitamin D status is typically a measure of circulating concentrations of 25-hydroxyvitamin D (25(OH)D). This measure is sometimes feasible and available in population studies, but often other surrogates are used instead. Yet the utility of a single measure of 25(OH)D to estimate long-term 25(OH)D status is not as simple as it may first appear. It is thus illustrative to consider factors that contribute to the variability in 25(OH)D level in a population.

In simple terms, one can think of measuring 25(OH)D in a given population and then examining the variation observed among the individuals. In most cases, there will be distribution of values, perhaps a normal distribution, with some individuals measuring high, some in the middle, and some low. A key question is what are the factors or determinants that ultimately determine whether a measurement is in the high or low range? Fig. 53.1 shows a pie chart of potential determinants of a measure of 25(OH)D. Each of these can contribute to the 25(OH)D level, and from a population perspective, these all can contribute to the variation in 25(OH)D levels. The actual proportions of each of the six factors in explaining variation of 25(OH)D will vary across populations and specific studies. As shown in Fig. 53.1, conceptually, we can think of at least six factors that could contribute to the variation of a single measure of 25(OH)D:

1. long-term modifiable determinants (e.g., vitamin D intake, sun exposure, body mass, region (latitude));
2. short-term determinants (e.g., seasonal variation, recent behaviors);

**FIGURE 53.1** Main sources of individual variation in a single 25(OH)D measure in a given population. The actual proportions will vary by the specific characteristics of the population.

3. genetic determinants;
4. epigenetic determinants;
5. pathophysiologic responses (e.g., systemic inflammation lowering 25(OH)D level);
6. laboratory measurement error.

For chronic diseases for which long-term vitamin D status is etiologically relevant, long-term determinants (1) are more important than short-term exposures (2). For outcomes for which current vitamin D status is important (e.g., acute infectious diseases), short-term exposures such as those due to seasonal (solar) variation may be relevant. Laboratory measurement error adds variation in 25(OH)D levels (6), but these do not reflect long-term status and can be considered as short-term determinants, that is, this error will cause differences in measures from the same individual taken at two separate time points. Measurement error does not reflect long-term actual differences and would generally weaken a true association between 25(OH)D and a disease if one exists.

Genetic determinants (3) are likely to be relevant for long-term status; however, if the genetic factors have biologic effects beyond influencing 25(OH)D levels, the 25(OH)D level determined by genetics may reflect biologic actions not related to vitamin D. Based on genome-wide association studies, only a small proportion of variation has been explained (<5%) [1]. For example, one study identified 69 independent common single nucleotide polymorphisms (SNPs) of genome-wide significant for 25(OH)D that explained 3.1% of the variance in 25(OH)D levels [2]. Although genetic factors appear to explain a relatively low proportion of the total variation in 25(OH)D, this variation is generally not associated with lifestyle factors such as intake or sun exposure behaviors. This lack of correlation between genetic and lifestyle factors can be exploited in Mendelian randomization studies, which can help determine causality of an association because any association observed

is unlikely to be caused by confounding from lifestyle factors (see [Section 4.5](#)).

Epigenetic determinants (4) [3] are likely to be important but currently are poorly understood. For example, it is known that individuals vary considerably in their change in 25(OH)D in response to a given intake of vitamin D, that is, some individuals will have a robust increase, and some will have minimal increase. These differences do not appear to be related to genetic factors primarily, so epigenetic determinants potentially could account for a significant amount of the variation of 25(OH)D levels. For example, in dosing studies of vitamin D on 25(OH)D blood levels, there is generally a wide variation in the individual response with no obvious explanation. One study suggested a potentially important role of epigenetics in determining 25(OH)D levels. Specifically, DNA methylation levels of cytochrome P450 (CYP) enzymes (CYP2R1, CYP24A1, CYP27A1, and CYP27B1) at CpG (cytosine–phosphate–guanine) islands predicted variation in raising 25(OH)D levels after vitamin D supplementation [4]. Epigenetic determinants likely contribute to variation in 25(OH)D levels, but the implications are not straightforward. For example, if infant or childhood deficiency of 25(OH)D results in an epigenetic response to upregulate 25(OH)D conversion, and this is carried over to adulthood, the higher 25(OH)D in adulthood may actually reflect in part deficiency of 25(OH)D earlier in life. Finally, pathophysiologic responses may be operative (5). One hypothesized relationship is that inflammation lowers 25(OH)D levels—thus, low 25(OH)D level may indirectly reflect inflammatory processes. As discussed in the following, this potential could affect inferences related to 25(OH)D level and disease.

Our goal in an epidemiologic study of chronic disease would be to acquire a long-term, time-integrated measure of 25(OH)D, the presumed measure of vitamin D status. Yet, a measure of 25(OH)D, especially a single measure over a course of one's lifetime, while very useful in studying etiology of disease, is a complex measure that is affected by many factors. Some of the factors displayed in [Fig. 53.1](#) may often add noise by being only short-term or cyclical such as seasonality (2) and measurement error (6), cause potential confounding (i.e., an association between low 25(OH)D status and higher risk of a disease may not reflect a causal association, but rather an association with inflammation) (5), or reflect complex relationships as a result of epigenetics (4).

## 2.2 Measures of circulating 25(OH)D

A measurement of circulating 25(OH)D incorporates the many factors that influence 25(OH)D status, both

cholecalciferol production from skin exposure to UV-B radiation and intake. Conceptually, if our goal is to assess cumulative long-term vitamin D status, on the order of decades for cancer, we might take frequent measures of 25(OH)D, say at monthly intervals over 10 years, and we presumably would get an excellent “gold standard” measure by averaging these. However, most studies typically only have access to a single measure of 25(OH)D, or a few at most. Thus, a critical question is how well a single measure would reflect long-term vitamin D status. Fortunately, 25(OH)D levels track over time so, in general, a single measure does reflect, albeit imperfectly, long-term 25(OH)D status. Limited data address the critical issue of how well a single measure is a good indicator of long-term vitamin D status. In one study of middle-aged to elderly US male health professionals, the correlation of two 25(OH)D measures ~3 years apart was 0.7 [5]. In another study of US men and women, the Spearman rank correlation coefficients comparing values at baseline to those taken within 1 year, 1 year apart, and 5 years apart were 0.65, 0.61, and 0.53, respectively [6]. In a Norwegian study, the correlation coefficient between serum 25(OH)D measurements taken at specific intervals from 1994 to 2008 ranged from 0.42 to 0.52 [7].

These correlations are reasonably high to be useful in etiologic studies. Yet, there are also secular trends in overall levels that may affect interpretation of results. For example, in the Canadian Multicentre Osteoporosis Study over a 10-year period starting in 1995–97, serum 25(OH)D increased by 9.3 (7.3–11.4) nmol/L in women and by 3.5 (0.6–6.4) nmol/L in men. Because of this increase, the percentage of participants with 25(OH)D concentrations <50 nmol/L was 29.7% at baseline and 19.8% at year 10 follow-up. Part, but not all of the increase, was due to an increase in vitamin D supplement use over the course of the study [8]. In the United States using national representative data from the National Health and Nutrition Examination Survey, vitamin D supplementation from sources other than multivitamins/multiminerals increased from 5.1% to 19% between 1999 and 2012 [9]. Overall, these findings suggest that 25(OH)D levels correlate reasonably well over time (for example, 5–15 years) for a single measure to provide meaningful results for epidemiologic studies. Nonetheless, there is some degree of measurement error, including some secular trends that can change absolute levels of 25(OH)D, which would tend to attenuate any real association.

A specific complexity in studies of 25(OH)D is that levels fluctuate throughout the year due to seasonal variances in sun exposure, so cases and controls are often matched for season of blood draw. One study provides a good example of adjusting for seasonal variation by regressing 25(OH)D concentrations in control

participants on week of blood draw using sine–cosine functions based on fluctuations of 25(OH)D throughout the year [10]. While matching or controlling for season reduces some extraneous variation in 25(OH)D level, it cannot overcome some potential limitations in a single measure. For example, if the nadir of 25(OH)D level in winter month is etiologically most relevant for a particular outcome, the samples that were collected in non-winter months may be less informative or even uninformative.

An additional important issue regards complexities in 25(OH)D measures using different assays and even within batches using the same assay. Having consistent reliable measures is critical in the formation of recommendations regarding absolute levels of 25(OH)D and disease risk. Technical issues related to measuring 25(OH)D are discussed in [Chapters 48–50](#). Based on available studies, some caution should be used when considering the absolute levels of 25(OH)D. Nonetheless, if cases and controls are matched and assayed in the same batch, then the relative ranking is valid if the assay has high interbatch reliability. Thus, studies to date are still useful in examining for differences in 25(OH)D levels between cases and noncases for hypothesis testing whether 25(OH)D levels are associated with a disease. In analyses that pool data from various studies, calibration of the various assays has proved useful [10]. However, some caution is required before establishing the actual quantitative dose–response relationship. Standardization of 25(OH)D tests in the future could ameliorate this issue. Additional issues regarding measures of “free” or “bioavailable” 25(OH)D due to the vitamin D binding protein are becoming more recognized and have been considered in a small number of epidemiologic studies to date. These may, or may not, become important in future epidemiologic studies, but are not considered in detail here, but can be referred to in [Chapter 7](#) of this book.

## 2.3 Measures of vitamin D intake

Vitamin D is relatively scarce in the common foods consumed by most populations. Moreover, not all populations fortify foods with vitamin D, and even when fortified, the amounts are relatively limited. For example, a glass of fortified milk (in the United States) contains only 100 IU vitamin D, a level that is small compared with amounts of vitamin D that can be formed on exposure to UV-B radiation [11,12]. In most populations, probably more vitamin D is made from sun exposure than is ingested through diet, though in some populations at high latitudes, vitamin D from marine sources may be the dominant sources. Thus, vitamin D intake may be an important contributor to 25(OH)D levels, especially

in winter months in regions at high latitudes [13]. During these time periods, intake may be the sole source, contributing vitamin D to the depleting sources of 25(OH)D accumulated in the summer and autumn. One important consideration of studies of vitamin D intake is that, depending on the specific population of interest, intake of vitamin D may be predominantly from one or a few sources, such as fatty fish, fortified milk or margarine, or supplements. Thus, dietary vitamin D intake will tend to be highly correlated with other dietary factors (e.g., omega-3 fatty acids in fish, calcium in milk, and other vitamins and minerals in supplements). If the correlation is very high (e.g., correlation coefficient >0.7), separating the influence of vitamin D from the correlated factor may be difficult from a statistical perspective.

An additional consideration is that ergocalciferol (D2) is often used in supplements, and ergocalciferol has been estimated to be less potent than cholecalciferol (D3) in raising 25(OH)D level [14]. Most databases do not take into account whether the source of vitamin D in supplements is from D2 or D3. In the past decade in the United States, the vitamin D dose available from supplements (including cholecalciferol) has increased and prevalence of use has increased. This change may increase the opportunity to conduct observational studies that can examine associations based on supplemental vitamin D intakes at higher levels.

## 2.4 Measures of sun exposure as a surrogate of vitamin D status

Because the major source of vitamin D is from sun exposure, some studies have used presumed sun exposure as a surrogate of vitamin D status. In some cases, especially in ecologic studies, solar UV-B based on factors such as latitude and cloud cover is used as the surrogate of vitamin D status on a population-wide basis. In some case–control and cohort studies, region and some questionnaire-based measures of sun exposure have been the measures used to assess potential vitamin D status on an individual basis. Some surrogates that have been used, such as sunburns or actinic damage from sun exposure, may represent relatively few extreme acute exposures to sun rather than frequent exposures that may be more relevant for vitamin D synthesis. Measurement error and possibly recall bias in case–control studies (discussed in the following) in assessing past exposures are issues that may potentially influence validity. The validity of using sun exposure as a surrogate of vitamin D status is strengthened if there is some evidence supporting that the surrogate used actually correlates with 25(OH)D level in the study setting.

Some objective methods to assess sun exposure, such as the use of reflectometry, have been utilized. For example, one case–control study of advanced prostate cancer was based on use of a reflectometer to measure overall sun exposure [15]. This method assesses the difference between facultative skin pigmentation on the forehead (a sun-exposed site) and constitutive pigmentation on the upper underarm (a sun-protected site). Then the difference between facultative and constitutive pigmentation is used to estimate sun exposure. In this study, sun exposure estimated by reflectometry was inversely associated with risk of advanced prostate cancer. Because these approaches do not directly quantify vitamin D status, they may offer support that individuals with higher potential exposure to UV-B that generates vitamin D are associated with an outcome, but they do not quantify the dose–response relationship between vitamin D status and disease risk. Most importantly, sun exposure could affect a disease by mechanisms other than production of vitamin D. For example, it has been hypothesized that solar ultraviolet (UV) radiation releases nitric oxide (NO) from storage forms in the skin, which can lower blood pressure [16]. If true, 25(OH)D as a measure of sun exposure could be associated with lower blood pressure, but this may not be a causal association.

## 2.5 Measures of predicted 25(OH)D levels

An additional approach to assess vitamin D status is to use known predictors of 25(OH)D level based on data on the individual level to formulate a predicted 25(OH)D score. The use of multiple determinants should provide a better estimate of 25(OH)D status than using a single determinant such as diet or region of residence. In one example of this approach, the predicted 25(OH)D score was formed and then examined in association with risk of colorectal cancer in men of the Health Professionals Follow-Up Study [17]. First, in a sample of 1095 men, actual plasma 25(OH)D level was the dependent variable in a multiple linear regression. The independent (predictor) variables were geographical region, race as a surrogate of skin pigmentation, dietary intake, supplement intake, body mass index, and leisure time physical activity, a surrogate of potential exposure to sunlight UV-B. Based on the regression coefficients, a score was calculated for each of ~47,000 cohort members who had information on these variables. This variable was then examined in relation to subsequent risk of incident colorectal cancer cases. In the multivariate analysis, a 25 nmol/L increment in 25(OH)D was associated with a 37% reduced risk of colorectal cancer. This association persisted after controlling for body mass index and physical activity.

The predicted 25(OH)D approach may have some advantages and disadvantages compared with the use of a

single measurement of circulating 25(OH)D in epidemiologic studies. The measurement of 25(OH)D is more direct and intuitive and incorporates some of the sources of variability of 25(OH)D not taken into account by the score. However, the predicted 25(OH)D measure may provide a reasonable measure of vitamin D status over a long period of time because some factors accounted for by the predicted 25(OH)D score are immutable (for example, skin color) or relatively stable (region of residence, body mass index), and these can be updated periodically (e.g., repeated dietary measures). In addition, a blood measure is prone to certain biases (see 4 and 5 in Fig. 53.1) discussed in the following and measurement error (Fig. 53.1, 7). Thus, although a predicted 25(OH)D will not capture all of the variation in circulating 25(OH)D, much of the extra variation in a measure of circulating 25(OH)D may actually contribute to noise and bias.

To assess the accuracy of the predicted 25(OH)D, the main method used is to compare the R-square of the model of predicted to actual 25(OH)D. Some of the reported R-squares (i.e., percentage of variation explained of a single 25(OH)D measure) have ranged from around 15% to 47% [18–21]. When compared with a single 25(OH)D level, the R-square for these “surrogates” have been typically considerably less than 50%, leading some to question the utility of this approach. Yet, the R-square may not be the best criterion to evaluate the potential usefulness of the predicted 25(OH)D score in epidemiologic studies. The argument that an R-square statistic reliably assesses validity assumes that a single measure of 25(OH)D is a perfect assessment of long-term 25(OH)D status, such as over a 10- or 20-year period. However, as summarized before, correlations between measures of 25(OH)D over a period of 3–10 years can be as low as 0.4 to 0.5. For a true “gold standard,” this correlation should be 1, or at least very close to it. Incorrectly, when considering the correlation between the actual measurement of 25(OH)D and the predicted 25(OH)D, all of the measurement error is assumed implicitly to be in the predicted score, but the inherent measurement error in a single 25(OH)D assessment to estimate long-term 25(OH)D status will dampen the correlation between the 25(OH)D measurement and the predicted score. Thus, the R-square between the 25(OH)D measurement and the predicted score should not be simply used to assess the ability of the predicted 25(OH)D measurement to estimate long-term 25(OH)D status.

A more useful criterion in evaluating the predicted 25(OH)D score to test a vitamin D–disease hypothesis is to consider the difference in long-term 25(OH)D tested by “high” and “low” exposure from the predicted 25(OH)D. Consider the example of an RCT of vitamin D and a chronic disease outcome. Two criteria we might

consider is (1) the increment in 25(OH)D caused by the study dose of vitamin D and (2) the time duration of the study. For example, a relevant question could be “does increasing 25(OH)D by 10 ng/mL for 10 years affect incidence of colorectal cancer?” Typically, RCTs of vitamin D present the mean 25(OH)D level in the treated group and the reference group, rather than the R-square of how well the treatment explains total variation in 25(OH)D status. The difference in the mean actual 25(OH)D levels in those with high versus low predicted scores incorporates both real variation in the population and measurement error from the questionnaire. For example, in three cohorts, the differences in mean actual 25(OH)D level between extreme deciles of predicted 25(OH)D score ranged from 9 to 12 ng/mL [22]. In actual cohort analyses with disease end point, to compute the predicted 25(OH)D score, repeated measures on diet and supplements every 2–4 years over a 30 year period can be incorporated. Notably, use of vitamin D supplements increased dramatically over time in the cohort; unlike a single measure of 25(OH)D, multiple questionnaire measures were able to account for the individual fluctuations of dietary and supplementary intakes of vitamin D (as well as other factors) over a 30-year period. In the Harvard cohorts, predicted 25(OH)D has provided comparable results to measured 25(OH)D for colorectal, pancreatic, and endometrial cancers [23–25]. Some have proposed using predicted 25(OH)D based on such data as region, sun exposure habit, as a screening tool for vitamin D deficiency [26].

## 2.6 Measure of genetic variation of circulating 25(OH)D

Genetic factors that affect 25(OH)D concentrations have been identified. For example, genetic variants around 7-dehydrocholesterol reductase (DHCR7) (rs7944926 and rs11234027) and CYP2R1 (rs10741657 and rs12794714) influence 25(OH)D levels either through synthesis of previtamin D from 7-dehydrocholesterol in the skin or through conversion of vitamin D to 25(OH)D in the liver [2]. These are relatively small determinants of 25(OH)D among all the determinants and explain only a small proportion of variation (<5%) in 25(OH)D concentrations. Yet, in adequately large study populations, statistically significant differences in mean 25(OH)D will be observed in individuals depending on their genetic variants. Furthermore, a genetic score can be formed based on multiple variants, with individuals possessing more of the variants associated with high 25(OH)D status having highest average 25(OH)D levels and those with fewest such variants with lowest average 25(OH)D. From an epidemiologic perspective, an advantage of the

variation in 25(OH)D due to genetics is that this will tend to be not associated or only weakly correlated with the nongenetic determinants of 25(OH)D (Fig. 53.1). This fact can be exploited in studies termed Mendelian Randomization studies, which examine the genetic association of 25(OH)D determinants with disease risk. These are discussed in Section 4.5).

## 3. Main challenges in the epidemiologic study of vitamin D and disease

There are numerous challenges in discerning causal associations in epidemiologic studies. While all these concerns are pertinent to studies in general, some are specifically relevant for studies of vitamin D. In particular, vitamin D status can be assessed in multiple ways, as discussed in this section, and how vitamin D status is assessed may have inherent advantages and limitations depending on the study question at hand. Four main criteria that need to be considered in assessing study validity are introduced in this section. These are each discussed in detail for each type of study design for the assessment of vitamin D status. This does not represent a list of all factors affecting validity in epidemiologic studies, but some of the major issues that should be considered specifically for epidemiologic studies of vitamin D are as follows:

### 3.1 The time period for the assessment of vitamin D status covered should be based on the pathogenesis of the disease end point of interest

Some effects of vitamin D, for example, on rapidly responding physiologic parameters such as blood pressure, could potentially, though not necessarily, become apparent relatively immediately as in days or weeks. In contrast, the effect on some exposures on multistage diseases that involve cumulative processes, such as cancer, may require assessments based on a longer time frame, such as years or even decades. The etiologically relevant time frame when vitamin D may be acting on the disease is critically important to consider. This point is often ignored. The time factor may be especially relevant for situations where early life exposure may influence risk of the disease in adulthood, or for diseases where there may be a long-time lag between the exposure and the appearance of the outcome. For example, it is becoming apparent that adolescence and early adulthood is a period where the risk of adult breast cancer [27] and prostate cancer [28] is especially prone to exposures. For multiple sclerosis, increasing data indicate that exposure to sun in childhood and adolescence (perhaps a

surrogate of vitamin D exposure) is associated with reduced risk later in life [29–31]. In many cases, the etiologically relevant time period is not known. In this case, “null” studies need to be interpreted conservatively as a true effect may have been missed by the study.

### 3.2 Studies ideally should assess the dose–response relationship

From a study of a given disease end point, it might not be adequate to conclude simply that higher vitamin D levels are beneficial. Rather, the dose–response relation should be estimated, which requires precise measures of vitamin D status. The probability of detecting an association in a study (assuming an association exists) depends on the range of vitamin D exposure in that population. This point is seen clearly in an RCT setting. In an RCT, the effect of an intervention may depend on the underlying vitamin D status of the population. For example, if nearly everyone in the study population is sufficient at baseline, no effect of the vitamin D intervention may be seen; if most people are vitamin D deficient at baseline, an effect may be observed if the intervention raises 25(OH)D levels to a therapeutic level. A special feature of vitamin D is that status is determined by dietary intake, supplement use, and sun exposure, and by endogenous factors such as obesity that influence 25(OH)D level. Some studies only measure one aspect of vitamin D status—for example, dietary intake or sun exposure measures or surrogates of sun exposure. While such studies may provide useful information to test the general hypothesis of interest, they do not assess the full dose–response relationship because only some of the determinants of vitamin D status are being addressed. Results from two studies may apparently conflict because the range of 25(OH)D assessed in the two studies was different, and the studies may have captured different ranges of the dose–response relation.

### 3.3 Biases should be reduced or eliminated to the extent possible

Bias refers to some mechanism in the data acquisition process that yields spurious associations in the study population. For example, let us assume that there is no association (neither causal nor noncausal) between dietary vitamin D intake and disease X in a population. If dietary data are collected with reasonable precision, then we would expect to see no association between vitamin D intake and disease X. However, in a case–control study, prediagnostic dietary data are inferred from retrospectively recalled dietary data; thus, it is possible that case and controls recall diets differently.

If so, a bias may occur. For example, more cases may contemplate on their past diet more extensively and thus are more likely to report higher dietary intakes than controls. This tendency can be considered recall bias. Of note, in a prospective cohort study, where diet information is collected before knowledge of disease outcome, recall bias is less likely. Of course, dietary information may not be recalled perfectly; however, because individuals do not know years in advance whether they will develop a disease or not, the errors of recall should be nondifferential relative to the future disease status. Such errors tend to produce nondifferential misclassification, adding “noise” to the measure, which would tend to obscure any associations that may exist. However, if an association is observed, it is unlikely to be caused by recall bias.

### 3.4 Confounding should be limited to the extent possible

The term “confounding” is often used nonspecifically as bias, but among epidemiologists, it has a precise meaning. Confounding occurs (1) when a causal factor for disease other than the one of primary interest exists in the population, and (2) this factor is statistically correlated with the primary factor of interest. This correlation between the factor of interest (e.g., vitamin D) and the other risk factor for disease produces a noncausal (spurious) association between the factor of interest and the disease. In the case of confounding, the information in a population may be collected accurately, but a noncausal association would still exist. For example, if physically active individuals are more likely to have higher 25(OH)D levels, then physical activity could be a potentially confounding factor for the vitamin D–disease association. If accurate information on physical activity were collected in the study, and proper statistical adjustments made, then the observed association between 25(OH)D and disease could be eliminated in the multivariable model adjusted for physical activity. Confounding can only be definitively excluded in an RCT, where the prevalence of all other factors is balanced between the treated and the placebo group. In observational studies, judgment must be made on the likelihood of confounding. In well-conducted prospective cohort studies, where biases can largely be excluded, confounding is the paramount factor to consider for a valid result, that is, an observed association is causal.

Fig. 53.1 provides a useful basis to consider the potential sources of confounding in studies of vitamin D. For a factor to exhibit confounding, it needs to have a statistical association with vitamin D status, and to be a risk factor for the disease of interest. The first group of potential confounders to consider are those factors that have a

direct relationship with 25(OH)D (1). For example, obesity is associated with lower 25(OH)D levels, and physical activity, which may increase opportunities for sun exposure, tends to be associated with higher 25(OH)D. These two factors, thus, need generally to be considered as potential confounders because they are risk factors for many diseases. If they are very strong risk factors for a specific disease, such as for type 2 diabetes mellitus, then the possibility of confounding is heightened. Some factors may not directly determine vitamin D status but could be confounders through correlated behaviors. For example, those who consume vitamin D supplements and thereby have higher 25(OH)D levels are also probably more likely to take other supplements (e.g., calcium or a multivitamin). Although these factors may not necessarily directly influence vitamin D status, because they have a statistical association with vitamin D through correlated behaviors, they are potential confounders if they are associated with the disease under study.

Short-term determinants of 25(OH)D (Fig. 53.1, 2) are generally not confounders, but rather add noise (extraneous variation) to any association with vitamin D and thus tend to cause underestimation of a true association. These errors should generally not cause a spurious association to arise if there is no true association.

Genetic determinants of 25(OH)D (Fig. 53.1, 3) are potentially useful in avoiding confounding because they tend not to be associated with many of the determinants of 25(OH)D, especially the ones related to behaviors. Thus, the association between a genetic determinant of 25(OH)D status and a disease will generally not be confounded by determinants such as physical activity, diet, or obesity. However, if a genetic variant utilized to determine 25(OH)D status has nonvitamin D functions in other pathways that are associated with the disease, this can cause a type of “genetic confounding” termed pleiotropy. The approach of using genetic determinants as a measure of vitamin D status has been termed Mendelian randomization and is discussed in the following.

Epigenetic determinants (Fig. 53.1, 4) are potential confounders, at least in principle, though this area is poorly understood. For example, if factor X early in life causes an upregulation of genes that convert vitamin D to 25(OH)D, then factor X could be a confounder if it is an independent determinant of the disease. As a theoretical illustrative example, assume poor vitamin D status early in life (e.g., low intake or low sun exposure) causes an upregulation of genes that enhance 25(OH) production through epigenetic mechanisms, and this upregulation is maintained later in life. This would cause higher 25(OH)D levels to be measured later in life; yet, paradoxically, this contribution to higher adult 25(OH)D may reflect a vitamin D deficiency early in life. Until we better understand what epigenetic determinants of

25(OH)D, it is not obvious how likely these are to be confounders.

Finally, a potentially important confounding factor is whether a pathophysiologic process, such as systemic inflammation, lowers 25(OH)D. In fact, this bias has been offered as a potential explanation of many of the associations observed between lower 25(OH)D levels and many chronic diseases [32]. The argument is that vitamin D would not be a causal factor for the disease, but rather low 25(OH)D levels would merely be a marker of chronic inflammation, the presumed causal factor. While plausible, this mechanism has not received extensive study. In one study, the inverse association between 25(OH)D level and risk of colorectal cancer in two cohorts persisted when the association was further adjusted for some markers of systemic inflammation [33]. This result provides some reassurance that the association between low 25(OH)D and colorectal cancer risk is not entirely due to low 25(OH)D reflecting an inflammatory state. In addition, complementary to the results for plasma 25(OH)D are studies based on predicted 25(OH)D, which show a similar association between low predicted 25(OH)D and colorectal cancer, but are not prone to this particular bias because 25(OH)D is not directly measured [16]. This topic deserves more study. A complicating factor is that some of the potential beneficial effects of vitamin D may be through a reduction of inflammation, so the directionality of the 25(OH)D—inflammatory marker direction requires better understanding [34].

#### 4. Summary of study designs of vitamin D

We consider five major types of study designs. These will be referred to as ecologic studies, cohort studies, case-control studies, randomized interventional studies, and Mendelian randomization studies. The nested case-control study, which is often utilized in studies of circulating 25(OH)D and disease, can technically be considered a case-control study, but because these are typically nested in prospective cohort studies, the issues related to validity are more similar to cohort studies than traditional case-control studies. Thus, nested case-control studies are considered a subset of cohort studies. The major issues affecting validity, summarized in *Main Challenges in the Epidemiologic Study of Vitamin D and Disease* (Section 3), are addressed specifically for each study design.

##### 4.1 Ecologic studies

Ecologic studies are based on examining rates of a disease in an entire population, rather than on an individual basis, and then to correlate some factor of interest based on the population average to the disease rates across

populations. For example, disease rates could be determined within countries, and then intercountry disease rates can be compared. The population can also be based on regions (e.g., states, provinces) within a country. In the context of vitamin D, the comparison that is inferred is typically the different average UV-B exposure as a surrogate of vitamin D status in the population. For example, building on work from Garland and Garland on colon cancer [35], Grant demonstrated that regional solar UV-B radiation inferred by region taking into account factors such as latitude, altitude, and cloud cover correlated inversely with mortality rates of numerous cancers, particularly digestive organ cancers [36]. Although rarely utilized, in principle the population average vitamin D status (e.g., 25(OH)D measurements taken on a representative sample of the entire population) can be used rather than surrogates. Studies of secular trends of a disease within a population are also possible. For example, disease rates following a population-wide intervention such as the implementation of vitamin D fortification can be examined. Insights and limitations from these ecologic studies are summarized here.

One potentially important advantage of ecologic studies is that if there is no substantial migration within the population, the exposure is lifelong. For example, those who have always lived in a sunny environment would have a lifelong potential for more vitamin D production than those who always lived in a less sunny region. If the time-relevant exposure for the disease of interest is early in life (childhood, adolescence), yet the disease typically occurs in middle or older ages, an association can possibly be captured in ecologic studies of geographical residence. In contrast, most serum-based cohorts are composed of middle-aged individuals, so the estimate of 25(OH)D will not reflect early life exposure, and an association for this example could be missed. In cohort and case-control studies, early life geographical residence could be used as a surrogate of past sun exposures and presumably vitamin D status at points earlier in life, at least based on region of residence. For some diseases, these earlier time periods could be most relevant. Ecologic studies are also feasibly done and can be utilized in many settings, providing a broad set of data.

On the downside, region is not a perfect surrogate of vitamin D status and does not take into account individuals' sun seeking or sun avoidance behaviors. Some populations may receive abundant sun but due to cultural or individual preferences may avoid the sun or wear clothing that blocks the sun. The main limitation for some ecologic studies may be the difficulty in controlling for various potential confounding factors. Some population-wide data can be used as covariables, such as average smoking rates, average body mass index, and average alcohol consumption. However, it is not clear if confounding can be adequately controlled

for in this manner because these data are not collected on an individual basis and data sources may vary across diverse populations. Large differences across many factors in populations, for example, in highly economically developed versus less developed countries, may be very difficult to take into account. There may be systematic differences across countries that confound the data. For example, in cancer studies, different rates of screening and detection of cancer across countries could influence apparent cancer incidence rates.

## 4.2 Cohort studies

The three main types of observational studies that assess exposure on an individual basis are cohort studies, case-control, and nested case-control studies. These are often referred to as analytic epidemiologic studies. In cohort studies, a study population is defined, and then vitamin D status is assessed on the individuals, who are then followed over time, often years, or decades, for occurrence of the disease end point of interest. The determination of disease outcome can be based on various methods, such as recontacting the participants for further information or linking to databases (e.g., cancer registries). Then rates of the disease can be compared, for example, in those who are deficient in vitamin D compared with those sufficient in vitamin D. Because vitamin D status is not randomized in the study population, but rather reflects factors such as diet, sun exposure behaviors, and genetics, statistical adjustments must typically be made to account for disease risk factors that could differ in the population by vitamin D status. These risk factors could cause confounding of the apparent vitamin D-disease association, which was discussed in more detail before. Because exposure information is collected before the disease occurs in cohort studies, these studies are often termed prospective studies or prospective cohort studies.

Vitamin D exposure can be assessed in various ways, as discussed in *Methods of Assessing Vitamin D Status* (Section 2). Typical methods are a circulating measure of 25(OH)D, or surrogates such as predicted 25(OH)D, dietary intake or sun exposure. Because information is collected prospectively in relation to disease occurrence, the cohort design can avoid many of the potential biases that may limit case-control studies. To avert many of the potential biases, the follow-up response rate of a cohort study should be high, for example, >90%. Because many biases can be avoided through use of the cohort design when the design and execution are strong, the main consideration for validity involves the assessment of potential for confounding. As discussed in *Main Challenges in the Epidemiologic Study of Vitamin D and Disease* (Section 3), it is critically important to

judge whether an association is causal or is confounded by another factor. When there is a null or weak result, consideration should be given to whether there was considerable measurement error of vitamin D, the range of vitamin D studied was within that of the dose–response relation, and whether the etiologically relevant time period was assessed. These factors would tend to obscure any relationship, rather than to generate a spurious association if none existed.

A nested case–control study has features both of a prospective cohort study and a case–control study. This study design is commonly used in biomarker studies, including that of circulating 25(OH)D. Unlike a typical case–control study, the study population is well defined, and all participants are identified from this population. Typically, the study population is based on an established cohort study, such as the Nurses’ Health Study, where participants have provided a blood specimen, which is then archived under stable, low-temperature conditions [37]. At the end of a defined follow-up period, such as 10 years, all cases of the outcome (disease) of interest are identified. For controls, a random sample is then selected from all the non-cases. When cases and the selected controls are identified, the blood samples are retrieved and assays (e.g., plasma 25(OH)D) are conducted. The data are analyzed according to a case–control design. The nested case–control design avoids certain biases such as selection bias and biases that may arise if the data are collected postdiagnostically. The trade-off versus a conventional cohort study is a small loss in statistical power, but the advantage is an enormous costs savings. In most cases, issues of biases in nested case–control studies should be considered similar as in cohort studies. Because the sample was taken before the diagnosis of cancer, it is unlikely that any association observed results spuriously from the cancer influencing the blood level (frequently called “reverse causation”). Reverse causation could occur in retrospective studies if the cancer itself or treatments cause metabolic changes that affect the 25(OH)D level, or if cancer leads to changes in behaviors (e.g., sun exposure reduced due to treatment or disability) that influence 25(OH)D levels. Thus, studies that have been based on the measurement of 25(OH)D in individuals already diagnosed with cancer need to be interpreted very cautiously because of the potential for the phenomenon of reverse causation. Even when 25(OH)D is measured prospectively, it is advisable to perform a lagged analysis excluding the first several years of follow-up to limit the reverse causation effect of undiagnosed latent disease.

### 4.3 Case–control studies

Case–control studies are studies in which individuals with the disease or end point of interest (cases)

are identified and an appropriate control group is identified. The exposure information (e.g., vitamin D status) is then assessed, typically retrospectively, in both the disease group and the control group. Conceptually, the control group should be a sample derived from all non-diseased individuals who, had they become cases, would have been included in the study as cases. For example, if a case–control study is defined as all cases of colorectal cancer diagnosed in New York City in 2000–04, the controls would be derived from all residents of New York City in this time period who, had they developed colorectal cancer, would have been included in the case set. Information of past vitamin D exposure is then assessed and compared in the case group and the control group. A case–control study can be efficient in the sense that one just needs a random sample of all residents for the study to be valid, at least in terms of selection. If a comparable cohort study were to be done in this example, all of the residents in New York City would have had to have vitamin D status assessed in 2004 and then all followed for colorectal cancer up to 2004. Such a study may not be feasible or prohibitively expensive. Case–control studies can be especially helpful in studying rare diseases because the underlying population in a cohort study would have to be very large to generate adequate case numbers.

In terms of issues of measurement of vitamin D (Issues 1 and 2 in *Methods of Assessing Vitamin D Status, Section 2*) and of confounding (Issue 4), the same considerations exist for case–control as for cohort studies. In addition, bias (Issue 3) is of particular concern in case–control studies [38]. We can consider two main types of potential biases, selection bias and information bias. Selection bias refers to biases in selection of proper controls. As described before, the control group should represent a random sample of individuals who, had they become cases during the study period, would have been identified as cases. In the aforementioned example of all residents from New York City, a practical means of identifying controls would be to use telephone numbers of all New York City residents as the population source. However, it is likely that some behaviors would relate to likelihood that a potential study participant if contacted would respond and agree to participate. If the response rate is low, then bias may occur. For example, it is possible that “health conscious” individuals who take a vitamin D supplement would be more likely to respond than those who do not. The study could then give biased results by making it appear that those who did not develop the disease were enriched with vitamin D supplement users. As response rates have tended to come down in population-based case–control studies in recent years [39], the potential for selection bias has increased. Other methods of selecting controls, such as the use of those hospitalized for other

reasons (than the disease of interest) presumably not related to vitamin D, can be utilized, though it is difficult to conclude that these conditions are not related to vitamin D. If they are, a bias would occur.

Information bias may occur when there is systematic error in the assessment of study information. The main concern is recall bias, which may occur because in a case–control study, information is collected after the case status is already known. If the information is based on recall, for example, of the typical diet 5–10 years before diagnosis, not only may there be error in general in both cases and controls (nondifferential error), but also there may be some differential error where cases have the tendency to over- or underreport intake. This type of bias can sometimes generate a spurious association. For example, cases may think more extensively over their past diet and thus may be less likely to forget food items. If the study involves a nonblinded interviewer, the interviewer may have unconscious biases in eliciting information because he or she is aware of the study question.

Objective biomarker studies are not a panacea for case–control studies, and perhaps can even be more prone for bias. If a blood sample to measure 25(OH)D is taken after diagnosis, changes in 25(OH)D may have occurred because of the disease. In this case, postdiagnostic 25(OH)D status is not an appropriate surrogate for prediagnostic 25(OH)D, the presumed etiologic factor. Some empirical data support that 25(OH)D level may decrease after a major disease diagnosis. For example, in breast cancer, very strong inverse associations between 25(OH)D and risk of breast cancer are observed in case–control studies, in contrast to prospective nested case–control studies, where little or much weaker associations are observed [40]. Some have offered the counterargument that as breast cancer may develop rapidly, case–control studies that measure 25(OH)D closer to the time of diagnosis (albeit after diagnosis) may capture the etiologic relevant time period better than cohort studies with a measure that can be years before the diagnosis [41,42]. If one is strictly interested in genetic factors (see Mendelian randomization studies in the following), case–control studies may provide valid results because genetic status would not change due to the diagnosis.

#### 4.4 Interventional studies (randomized controlled trials)

Intervention or experimental studies are those designed so that the investigator assigns vitamin D exposure, rather than just observing vitamin D status that occurred naturally in the population. A double-blinded, placebo-controlled, randomized intervention

(RCT) is widely accepted as the “gold standard” in establishing a causal association. In this study design, vitamin D status is conferred to the subject randomly by the investigator. The investigator and the subject are blinded to vitamin D assignment until the data analysis stage to prevent any bias. If randomization is successful, typically ensured by a sufficiently large study size, then all other known and unknown determinants of the disease should be equally distributed and uncorrelated to vitamin D status. If an association between vitamin D and outcome is observed, and chance ruled out by a sufficiently large study, then one may infer that the association between vitamin D and the end point is causal. Any other factors that may have contributed to risk of the disease should have been balanced equally in frequency between the vitamin D assigned group and the placebo group. Thus, the vitamin D is the only factor that could have contributed to the difference in disease rates in the treated and placebo groups.

While deceptively simple in concept, “definitive” RCTs are difficult to execute [43]. Because of the expense of performing RCTs of vitamin D and many outcomes of interest, randomized studies are rare for some end points. Although considered the gold standard in addressing causality, in practice, RCTs have a number of practical limitations. The selection of the effective dose may be problematic. Unlike as for a drug, everyone has an underlying baseline level of 25(OH)D, and thus the potential for benefit likely varies among the subjects; those with adequate vitamin D may not benefit from the study intervention and may contribute to null results [44]. For cardiovascular disease, both observational studies of circulating 25(OH)D [45] and dose–response Mendelian randomization studies suggest low 25(OH)D is associated with increased risk only at very low levels, such as below 25 nmol/L [46]. A benefit of vitamin D supplementation has not been confirmed in RCTs, but it is possible that most of the subjects enrolled had levels exceeding the level where any benefit plateaued. For example, in the VITamin D and Omega-3 Trial (VITAL), the mean baseline 25(OH)D level was about 75 nmol/L, so it is unlikely that many subjects had sufficiently low levels to experience a benefit [47].

In addition, there may be poor compliance and contamination by the placebo group adopting the change (for example, taking vitamin D supplements outside of the study protocol). In some cases, the necessary duration for the study may not be adequate to show an effect for a cancer outcome. Finally, the period of time during the long natural history of cancer where vitamin D action is relevant is unknown. For example, in autoimmune diseases such as multiple sclerosis, it may be relatively feasible to design an RCT to examine if vitamin D

reduces progression of the disease, but it is extremely difficult to demonstrate if vitamin D deficiency in infancy and childhood predispose to multiple sclerosis risk in adulthood.

When a well-designed and effectively executed RCT elicits a positive finding, this result may provide strong or even compelling evidence of support for the hypothesis. The largest primary prevention RCT to date is VITAL, a United States nationwide, randomized, placebo-controlled,  $2 \times 2$  factorial trial of vitamin D<sub>3</sub> (cholecalciferol, 2000 IU/day) and marine omega-3 fatty acids (1 g/day) for the prevention of cancer and cardiovascular disease and other major outcomes [47–49]. Another example is the D-Health Trial, which was initiated to determine if supplementing an older population with high monthly doses of vitamin D (60,000 IU of cholecalciferol) can prevent cancer and premature mortality [63]. This trial differs from VITAL in providing infrequent bolus dosing in contrast to daily dosing. Because of the limitations enumerated before, when these studies show a null association, caution must be given not to have undue confidence in the results. Besides correctly reflecting the absence of a true association, one or more of the limitations mentioned before could produce a null association in an RCT.

An important consideration in RCTs that is not relevant for most other types of evidence is that some trials have used bolus dosing. The degree of bolus dosing can vary; for example, some trials have used doses of cholecalciferol ranging from 20,000 IU/week to 500,000 IU/year. In fact, evidence from RCTs suggests that large bolus dosing of vitamin D may have minimal or possibly adverse effects on various outcomes, including rickets, falls, fractures, and respiratory infections [50]. Although bolus dosing is usually effective in increasing 25(OH)D levels, vitamin D (cholecalciferol) is rapidly cleared from the circulation and becomes undetectable in the circulation after about 1 week. Hollis and Wagner have argued that many cell types possess 25 hydroxylase and  $1\alpha$ -hydroxylase activities and are thus capable of converting vitamin D to the active metabolites [51]. This autocrine production of 25(OH)D precludes the requirement of vitamin D hydroxylations in the liver and kidney [11]. Furthermore, because of its low binding affinity to vitamin D-binding protein, vitamin D diffuses into cells more readily than 25(OH)D, which is bound tightly to the vitamin D-binding protein. Furthermore, large-bolus dosing activates the enzyme 24-hydroxylase (CYP24A1), which results in catabolism of 1,25(OH)<sub>2</sub>D [50]. It is plausible that maintaining daily high levels of vitamin D is physiologically superior to infrequent large-dose bolus, even if the same level of circulating 25(OH)D is achieved.

## 4.5 Mendelian randomization studies

A genetic approach to study causation in epidemiologic studies is based on the concept of “Mendelian randomization.” These studies are discussed in more detail in Chapter 62 of this book. In recent years, Mendelian randomization has been applied to the study of nutrition and diseases, including vitamin D [52]. The basic premise of Mendelian randomization is that a person’s genetic variation is generally not correlated to nongenetic cancer risk factors. Thus, if the relationship of 25(OH)D and a disease endpoint were to be causal, an association would be expected between the genetic variants (e.g., single nucleotide polymorphisms or SNPs) that predict levels of 25(OH)D and cancer risk. Mendelian randomization is a useful approach, but assumptions must be clearly understood and evaluated if feasible. The first assumption is a gene–environment equivalence assumption, that is, the genetic effect is equivalent to a comparable environmental effect. For example, a 10 nmol/L increment in 25(OH)D caused by supplementation would yield a similar result on an outcome as a 10 nmol/L difference in individuals resulting from genetic variation. Based on formal instrumental variable analysis, there are three important assumptions. The “relevance” assumption requires that the genetic variants that are being used as an instrument variable are robustly associated with the exposure; the “independence” or “exchangeability” assumption requires that no common causes of the genetic variants and outcome exist (examples include population substructure, assortative mating and dynastic effects); and the “exclusion restriction” assumption requires no independent pathway exists between the genetic variants and outcome other than through the exposure, also known as horizontal pleiotropy. If these requirements are met, Mendelian randomization can provide independent evidence for an association and would suggest that association is causal. Although spurious associations could occur in Mendelian randomization studies, the potential biases and confounding are unlikely to be similar as in conventional observational studies (e.g., cohort studies), so a convergence of results by different approaches increases the likelihood of causality.

The identified genetic variants for 25(OH)D explain a small amount of variation (<5%) of 25(OH)D levels, so the predicted reduction in risk would be small and perhaps undetectable in some studies. Exceptionally large studies are usually required for adequate power. Furthermore, because some of the SNPs associated with 25(OH)D levels also influence vitamin D binding protein concentration and the affinity for 25(OH)D, these SNPs also alter 25(OH)D bioavailability (free

hormone) independently of total 25(OH)D concentration potentially invalidating the “independence” or “exchangeability” Mendelian randomization assumption. For example, possession of the DBP2-encoding variant (rs4588\*A) is associated with lower 25(OH)D levels, but some studies suggest that this DBP2 isoform also has the lowest binding affinity to 25(OH)D, leading to higher levels of free 25(OH)D [53,54]. This, perhaps this variant could lead to both lower total 25(OH)D levels and potentially higher free 25(OH)D levels. If free 25(OH)D is the causal factor for an endpoint, the inverse relationship between total and free 25(OH)D could complicate inferences from studies based on the genetic variation of total 25(OH)D.

Mendelian randomization has been utilized in vitamin D studies for various endpoints. One very large study based in 326,409 UK Biobank Europeans examined the causal relations between 25(OH)D and 106 diseases/traits based on Mendelian randomization analysis using 143 genome-wide significant 25(OH)D-associated variants [55]. The analyses from this study supported a potential causal role of 25(OH)D in increasing height and preventing ovarian cancer, multiple sclerosis, leg fracture, and femur fracture. One study examined 95,766 Danish white participants from three cohorts who were genotyped for genetic variants in *DHCR7* and *CYP2R1* [56], genes affecting plasma 25(OH)D concentrations through synthesis. Plasma 25(OH)D was also measured. Lower measured 25(OH)D levels were associated with an increased risk of all-cause mortality, cardiovascular mortality, cancer mortality, and other-cause mortality. Lower genetically determined 25(OH)D levels were associated with an increased risk of all-cause mortality, cancer mortality, and other cause mortality, but were not associated with lower risk of cardiovascular mortality. These results from this Mendelian randomization study support the observational results of an association between lower 25(OH)D and all-cause mortality, cancer mortality, and other mortality but not for cardiovascular mortality. A broad protective effect on cancer incidence (except ovarian cancer) has not been demonstrated by Mendelian randomization studies [57]. Mendelian randomization studies provide robust support for genetically low 25(OH)D and multiple sclerosis [55,58–60]. These data suggest that Mendelian randomization studies may contribute to the study of vitamin D and disease.

## 5. Conclusions

Population-based association studies are an important component of the overall body of evidence for a given association. The overall synthesis of evidence for an association should include the evaluation of studies

that provide mechanistic insights, including in vitro investigations, animal studies, and human experimental studies on intermediate factors for the end point of interest. Mechanistic studies are important for ascribing causality to observed associations. However, the complexity and multifactorial nature of chronic diseases that occur over many years or decades in free-living populations often preclude simple extrapolations. Even if a causal association is assumed, the dose–response relationship and the etiologic relevant time period when the association may be actively influencing disease risk may not be known. Intermediate markers of a disease may include hormonal, metabolic, immunological, and epigenetic responses, but how these intermediates ultimately relate to a chronic disease may not always be a simple matter because diseases are multifactorial and may develop in stages over many years or decades. Laboratory studies in cell culture or animals permit hypothesis testing under controlled conditions to a greater degree than is feasible in free-living human populations, but results may not be directly generalizable to humans. Population-based studies provide critical information for dose–response, temporality of an association, and for identifying susceptible subgroups of individuals.

Causality of an association can be best established in RCTs, but the utility of RCTs may depend on the specifics of the outcome of interest. RCTs are most useful in testing hypotheses for common end points or a physiologic parameter (such as blood pressure) for which a short-term effect may be predicted. The numbers required may be manageable, and the time required is short enough to ensure high compliance. Susceptible groups (e.g., those with low baseline 25(OH)D who may be most likely to benefit) may be selected. In such cases, RCTs could feasibly generate definitive results. Some large randomized studies conducted over the past decade (e.g., VITAL, D HEalth study) are beginning to yield important information for chronic diseases [47]. PMID: 30886934. Typical intervention times for such RCTs are approximately 5 years.

Intervention periods of 5 years are reasonably long, but important associations could still be missed. Some diseases may have periods of susceptibility and long-time lags to observe an effect. For example, RCTs of aspirin and colorectal cancer only show a benefit emerging after about 10 years from the onset of the intervention [61]. Another example is breast cancer, where the period of breast growth in adolescence is a particularly critical time for exposures to exert effects [62]. RCTs are unlikely to provide definitive data for the hypothesis that vitamin D status during this time influences breast cancer risk. Even standard epidemiologic studies of circulating 25(OH)D assessed in middle or older age would be inadequate in testing the hypothesis that early-life exposure to vitamin D influences breast

cancer risk. Mendelian randomization studies might be useful as the genetic “exposure” should presumably be lifelong and encompass early-life effects.

Often, judgments must be based primarily on observational data, along with supporting mechanistic data. This chapter summarized five different methods to assess vitamin D status, four major considerations in studies to assess validity, and five major types of study designs. These criteria are useful in assessing the likelihood of a study providing a valid result, that is, if an association is observed, whether it is causal rather than reflecting bias or confounding. The use of a biologic measurement of 25(OH)D has been useful in epidemiologic studies, but caution is required in interpretation. As summarized in Fig. 53.1, there are multiple determinants in the variation of 25(OH)D, and some would not reflect a causal association. In fact, if 25(OH)D level were influenced by a process such as inflammation, the potential for confounding (“reverse causation”) would be serious. Complementary studies of vitamin D intake, sun exposure and predicted 25(OH)D would be useful because, while they have their own limitations, they would not be prone to this same bias.

A more recent research approach with substantial potential is Mendelian randomization. A limitation is that only a small proportion of 25(OH)D is explained by genetic factors involved in determining 25(OH)D status, so very large studies are required. When they yield positive results, these studies add to the argument of causality because confounding from lifestyle determinants of 25(OH)D is unlikely to be significant. Mendelian randomization studies can be complementary but would not inform on the dose–response relationship or on the time period of action because presumably the genetic “dose” would extend across the lifespan and one could not tell when vitamin D actions are relevant. That the genetic “exposure” is lifelong is useful in detecting an association, but if one is observed, it may be difficult to tell when in the life course the exposure is most etiologically relevant.

Many lines of evidence contribute to the establishment of a causal association. Because different approaches would have different strengths and limitations, consistency of findings across many different study designs would strengthen the argument for causality. Consistency across populations would also be important. For example, if an association with vitamin D is observed both in populations where most vitamin D is from sun exposure or and in populations where dietary sources of vitamin D are most important, this finding would tend to argue against a single confounding factor explaining the associations. While appropriately conducted RCTs may be required to establish a causal association, all available evidence should be incorporated into determining the relevant timing in the life course, the dose–response, and susceptible populations.

## 6. Summary points

- Randomized controlled trials are considered the highest level of evidence to establish a causal association between vitamin D and various health and disease outcomes.
- Observational studies remain important and complementary to randomized trials, as they can examine associations in very large numbers, for long durations and for wide ranges in vitamin D status, in susceptible subgroups, and can help establish dose–response relationships.
- There are multiple ways to assess vitamin D status, including direct measures of circulating 25(OH)D, dietary and supplementary intake, sun exposure as a surrogate, genetic determinants (Mendelian randomization), and a combination of predictors of vitamin D status.
- It is critical to consider the specific strengths and limitations of the various methods to assess vitamin D.
- Observational study designs include ecologic studies, cohort (prospective) studies, case–control studies, and Mendelian randomization studies. Each has specific strengths and limitations to when considering the potential for bias and confounding to provide invalid results. In general, cohort studies based on measures of circulating 25(OH)D are considered the strongest type of observational studies.
- The best conclusion is made when results from different study designs, which tend to have different sources of biases, converge on similar results.

## OBJECTIVES

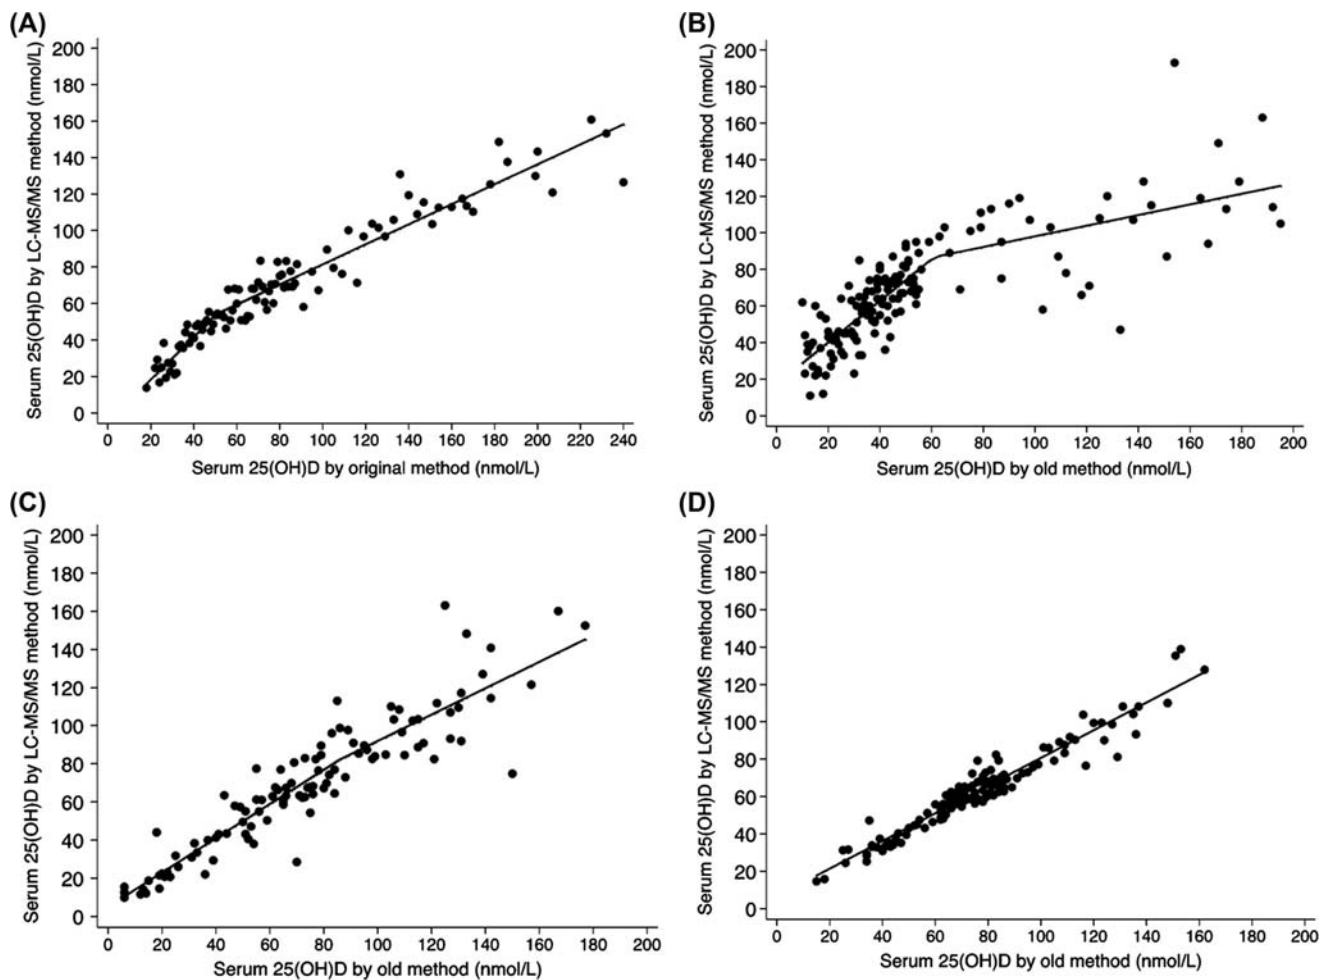

- After reading the chapter, the reader should have insight in the assessment of vitamin D status and the necessary quality control, the worldwide vitamin D status, and the prevalence of vitamin D deficiency and insufficiency throughout continents and countries.
- The reader will also be able to identify vitamin D deficiency high-risk groups.
- The chapter will also describe the influence of nutrition, ethnicity and migration on vitamin D deficiency.
- The chapter will also detail trends in vitamin D status during the last decades, and the implications of the findings.

## 1. Introduction

Vitamin D status has been determined in numerous studies covering all continents and many countries. The measurement of serum concentrations of 25-hydroxyvitamin D (25(OH)D) is used to assess vitamin D status, to diagnose vitamin D deficiency, and to determine the effect of vitamin D supplementation. There is not yet consensus on the required serum 25(OH)D concentration for optimal health. However, most clinicians agree that clinical vitamin D deficiency only occurs when serum 25(OH)D is lower than 25 nmol/L (10 ng/mL) [1,2]. According to the Institute of Medicine,

vitamin D deficiency occurs when the serum concentration 25(OH)D concentration is below 30 nmol/L [3]. Opinions differ on whether the required serum 25(OH)D for optimal bone mineral density, bone turnover, muscle strength, and nonclassical effects should be above 50 nmol/L, 75 nmol/L, or higher [4,5] (differing opinions are discussed in Chapter 51 and Chapter 52).

Another related problem, when comparing vitamin D status between countries, results from assay differences between various studies [6]. These differences may result in bias of 25% between 25(OH)D measurements resulting in large differences in the segment of the population that should be treated for inadequate vitamin D status [7]. Over the past decade, efforts have been made to standardize 25(OH)D assays. Liquid chromatography, followed by tandem mass spectrometry (LC-MS/MS), has become the method of choice due to its better precision compared with immune-based methods (see Chapter 48). The Vitamin D External Quality Assessment Scheme (DEQAS) distributes sera to more than 1000 laboratories and provides the results as the difference from the overall mean value [8]. The Vitamin D Standardization Program (VDSP) uses standards provided by the National Institute of Standardization Technology to improve the accuracy of the assays [9,10] (see Chapter 49). This facilitates comparison between current surveys of vitamin D (25(OH)D) status (Fig. 54.1). However, epidemiological studies done in the past can also be standardized when frozen samples are available. This enables unbiased comparison between different countries and different studies as carried out for the food-based solutions for optimal vitamin D nutrition and health through the life cycle (ODIN) study [11].

**FIGURE 54.1** Standardization according to Vitamin D Standardization Program (VDSP) protocol. The relationship between serum 25(OH)D in a subsample of the Health 2011 (A), Oslo Health (B), Health 2006 (C), and VitmaD (D) samples measured by original 25(OH)D assay and standardized LC-MS/MS at University College Cork. Ref. [10].

Vitamin D status depends on the available amount of ultraviolet light in the sunlight, which varies with latitude and season, on actual sunlight exposure and on skin pigmentation, and the use of sunscreen and clothing (see [Chapter 3](#)). The latter also varies depending on cultural and religious background. The lower the actual sun exposure, the more nutrition becomes important, especially the consumption of oily fish, vitamin D–fortified foods, and vitamin D supplements (see [Chapter 55](#)). In the following paragraphs, vitamin D status and the occurrence of vitamin D insufficiency and deficiency will be discussed in different continents, North America, South America, Europe, Middle East, Asia, Africa, and Oceania. Vitamin D deficiency will be defined as serum 25(OH)D < 25 nmol/L, unless stated otherwise. The number of surveys on vitamin D status is ever growing, and excellent reviews have been published in recent years [12,13]. In the current review, we have included a selection of studies published in the past decade, i.e., from 2011 onward. Subsequently,

studies on vitamin D status in one or more continents performed in a central laboratory will be presented. In these studies, interlaboratory variation in serum 25(OH)D assays does not play a role. In the next sections, ethnic issues and nutrition will be discussed as far as these have consequences for vitamin D status in different countries and continents. In addition, risk groups will be identified and discussed. In the final section, the consequences, i.e., the part of the population that is vitamin D deficient or vitamin D insufficient will be discussed, and finally, conclusions will be drawn.

## 2. Assessment of vitamin D status

Vitamin D status is usually assessed by measuring 25(OH)D in plasma or serum. The assay methods can be divided in immunological methods, including radioimmunoassay and chemiluminescent immunological assay, and chromatographic techniques, including

high-performance liquid chromatography (HPLC) and LC-MS/MS [14] (see Chapter 48). The chromatographic methods have a lower variation and are less subject to bias than the immunological methods. Currently, LC-MS/MS is considered the gold standard. DEQAS follows more than 1000 laboratories worldwide by sending samples, collecting the results, and plotting the values around the general mean [14]. With the VDSP, recent and older population studies within Europe have been cross-calibrated and standardized in the ODIN study [11].

### 3. Study selection

Many reviews on vitamin D status throughout continents or worldwide have been published in the past decade [12,13,15,16]. For this chapter, our aim was to give an overview of the vitamin D status worldwide without attempting to be complete. A search was done in PubMed using the following search strategy: (“2016/07/01”[Date—Publication]: “2022/01/10”[Date—Publication]), and (“Vitamin D”[Mesh] “Vitamin D deficiency”[Mesh]) and (“prevalence”[tw] “population”[tw]), specified according to continents. Studies between 2011 and 2016 were selected from the former edition of this chapter. We sought for studies preferably with more than 1000 subjects, population-based studies rather than convenience samples or biobank studies. When more studies were available for one country, we selected studies with standardized assessment of 25(OH)D or those that used chromatographic (preferably LC-MS) instead of immunological methods. Many regions in the world just recently started with vitamin D assessment in their population, and quality assessment may not be always according to the highest standards. Studies from these regions or countries were not available in the former edition of the vitamin D book. For the fifth edition of the vitamin D book, we made an attempt to cover most regions and countries of the world.

#### 3.1 Vitamin D status in North America (including Canada and Mexico)

Several large studies examined the vitamin D status in North America. Data of a selection of studies are shown in Table 54.1. The table includes data on country, latitude, study population, age, serum 25(OH)D assay method, mean levels of serum 25(OH)D in nmol/L, and percentage of the population with serum 25(OH)D below 25 nmol/L and below 50 nmol/L if available.

In North America (including Canada and Mexico), the latitudes ranged from 76°N to 19°N. The largest study is the National Health and Nutrition Examination

Survey (NHANES). This US study comprised a large, nationally representative sample and presents the vitamin D status of men and women, in different age groups, and according to different ethnic backgrounds [25,26]. The most recent of these two studies reported the vitamin D status of 16,180 persons aged 1 year or older in the period 2011–14 [25]. The prevalence of vitamin D deficiency (<30 nmol/L) was slightly lower in men (4.4%) than in women (5.7%). Furthermore, the prevalence was lowest in 1 to 5-year-olds (0.5%), peaked in adults aged 20–39 years (7.6%), and was lower again in adults aged 60 years and older (2.9%) [25]. Finally, the prevalence was highest in non-Hispanic black (17.5%) and lowest in non-Hispanic white (2.1%) [25]. In the Canadian Health Measure Survey (n = 11,009), males had lower 25(OH)D levels than females, and immigrants had lower serum 25(OH)D than nonimmigrants. Furthermore, the lowest 25(OH)D levels were found in the age groups 12–17 years (55.8 nmol/L) and 18–64 years (58.5 nmol/L) as compared with the age groups <5, 5–11, >64 years [17]. A relatively high prevalence of vitamin D deficiency (<25 nmol/L) was observed in refugee women in Canada (21%) [21] and in pregnant women in the United States (22.3% < 30 nmol/L) [28]. In addition, high prevalence rates of low vitamin D status (<37.5 nmol/L) were found in neonates (23%–31%) and in cord blood (38.9%) [32,35,40]. In a review of studies in Aboriginal groups in the Canadian Arctic, the prevalence of low vitamin D status ranged from 13.9% to 76.0% among children and adults in the summer [44].

#### 3.2 Vitamin D status in South America

During the past decade, many studies have been published on vitamin D status in South American countries (Table 54.2). Latitudes range from 4°N to 33°S. By far, most studies were published in Brazil. In a metaanalysis of 72 Brazilian studies, the mean serum 25(OH)D status was 67.7 nmol/L in the period 2000–17 and 28.2% had a serum 25(OH)D level below 50 nmol/L [84]. In several studies, a very high prevalence of persons having serum 25(OH)D below 50 nmol/L was observed, especially in Colombian toddlers (42.5%) [45], Brazilian children aged 11–15 months (68.2%) [49], community-dwelling elderly in Sao Paulo, Brazil (58.0%) [76], female Xavante Indians (43.4%) [73], Koya Indian children living in Argentina (96.6%) [80], healthy adults aged >60 years from Chile (48.0%) [82], and adult and older women from Chile (51.6% and 64.9%, respectively) [83]. In another study, performed in a random sample of elderly in Brazil, 40.8% had a serum 25(OH)D < 75 nmol/L [53]. Finally, 71.2% of nursing home residents living in Natal, Brazil, had a serum 25(OH)D < 30 nmol/L [51].

### 3.3 Vitamin D status in Europe

Vitamin D status has been studied extensively in many European countries in different age groups (Table 54.3). Recently, a review on current vitamin D status in European and Middle East countries and strategies to prevent vitamin D deficiency has been published [16]. Last years, more studies from Eastern Europe have been published, as well as a review paper [111]. Data from Iceland, Norway, Ireland, the United Kingdom, the Netherlands, Germany, and Greece have recently been standardized by the European ODIN study [11], making all these data comparable. In the ODIN Study serum 25(OH)D was lower than 30 nmol/L in 12.5% of the participants and lower than 50 nmol/L in 40%. A general trend in these data was that vitamin D status was usually better in Nordic countries than around the Mediterranean despite higher latitude. This difference may be caused by the traditional high intake of cod, cod liver, and cod liver oil in Norway and Sweden [112]. In Finland, fortification of dairy products has been increased in two steps, leading to a formidable improvement of vitamin D status [88]. Representative data have been obtained in the United Kingdom in the National Dietary and Nutrition Survey [113] (Fig. 54.2). As expected, serum 25(OH)D was lower in older persons than in adults. Unexpectedly, serum 25(OH)D was low in adolescents [11,91]. Vitamin D status was poor in older persons and patients with hip fracture and the institutionalized. Similarly, very low serum 25(OH)D levels were observed in noninstitutionalized elderly in Switzerland. Also, in Italy and Greece, very low serum 25(OH)D levels were observed, while sunshine is abundant in these countries. This may be caused by a more pigmented skin and by sun avoidance behavior especially in summer because of the high temperatures. Vitamin D status usually is very poor in immigrants from non-Western countries [114,115], compared with native people (Fig. 54.3). This is even worse in pregnant non-Western immigrants, in which mean serum 25(OH)D was lower than 25 nmol/L in midwives practices in the Hague [116].

### 3.4 Vitamin D status in Middle East

Serum 25(OH)D is lower in these countries than should be expected based on the abundance of sunshine (Table 54.4). A recent review on vitamin D status in the Middle East showed widespread vitamin D deficiency [134]. In Turkey, Saudi Arabia and Kuwait serum 25(OH)D was lower in women than in men [119,127,130]. In women, vitamin D status depended on clothing style being lower in traditionally clothed

women than in women with Western style clothing. A very low serum 25(OH)D was observed in Saudi Arabia even with the very sunny climate. This may be explained by the often completely covered skin in this country. Similar trends were visible in Egypt and Iran. Another possible explanation for the low levels of 25(OH)D in this part of the world is the extreme heat, leading people to avoid being outdoors during the sunny parts of the day.

### 3.5 Vitamin D status in Asia

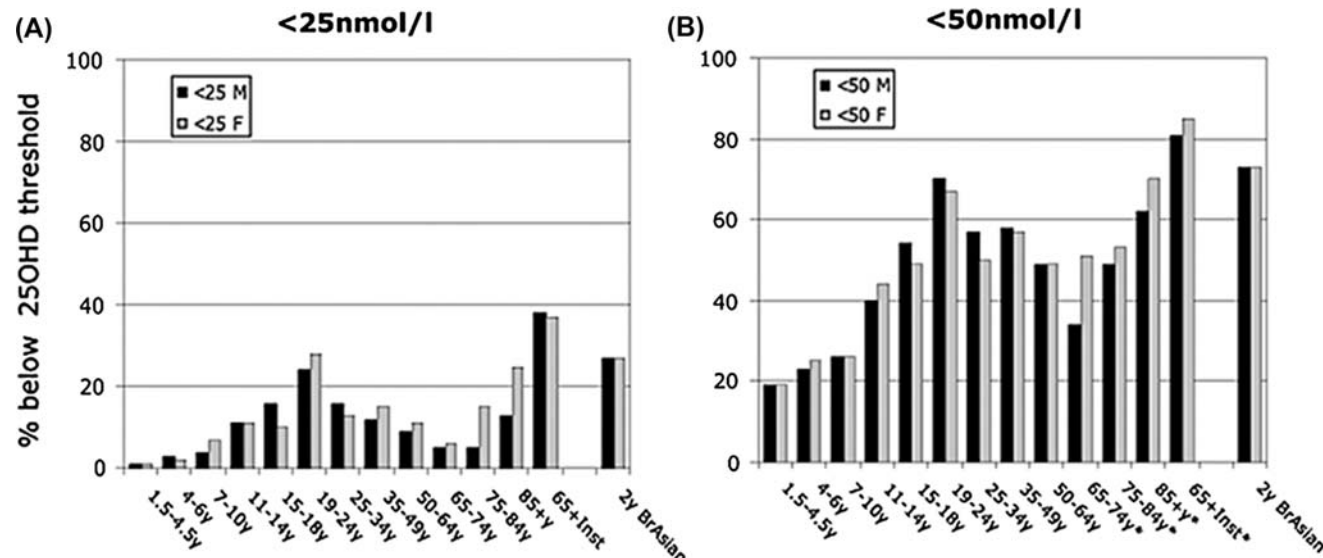

Recently, many studies on vitamin D status in Asian countries have been published although there remain Asian countries with a complete lack of published data such as Myanmar and Uzbekistan (Table 54.5). A very low vitamin D status was observed in Mongolia with a prevalence of serum 25(OH)D below 25 nmol/L in 88.6% of the young women and around 40% of children [135–137]. Clinical signs of rickets are still very common in Mongolia [113,136]. Most studies on vitamin D status in Asia have been performed in China. A nationwide population-based study demonstrated 25(OH)D levels below 50 nmol/L in 80% of the children above 6 years old [143]. Also, very high prevalence of 25(OH)D concentration below 50 nmol/L is reported in lactating women in China (97.9%) [148]. Large differences in vitamin D status in China are observed dependent on latitude and altitude [138,141,142,144]. For example, a very high prevalence of 25(OH)D concentrations below 50 nmol/L of 82.2% was observed in women living in a sunlight-deprived basin in Sichuan and a very low prevalence of 2.9% in adults living in Hainan, a tropical island province in southern China [138,141]. A recent review demonstrated that within the South Asian countries (Bangladesh, India, Pakistan, Nepal, Bhutan, Maldives, Sri Lanka, and Afghanistan), 25(OH)D concentrations below 50 nmol/L are more common than would be expected from the latitude.

The highest prevalence of 25-hydroxyvitamin D concentrations below 50 nmol/L within the South Asian countries was found in Pakistan (73%) followed by Bangladesh (67%), India (67%), Nepal (57%), and Sri Lanka (48%) [176]. This may be due to pigmented skin, skin covering, and sun avoidance behavior. Also, air pollution probably plays a role as 25(OH)D concentrations are particularly low in large cities such as Delhi with mean concentration of 20–25 nmol/L in adults [168,170]. Among Southeast Asian countries such as Singapore, Thailand, Cambodia, Taiwan, and Malaysia, vitamin D status is much better probably mainly because these Asian countries are localized closest to the equator.

**TABLE 54.3** Vitamin D status and prevalence of vitamin D deficiency in different European countries.

**FIGURE 54.2** Percentage of the population in the United Kingdom with serum 25-hydroxyvitamin D lower than 25 nmol/L (vitamin D deficiency) or lower than 50 nmol/L (vitamin D deficiency and low vitamin D status). Data from the National Dietary and Nutrition Survey [113]. The prevalence of low serum 25(OH)D levels is remarkably high in adolescents and young adults.

### 3.6 Vitamin D status in Africa

Africa is the continent with most sun hours per year and the largest exposure to UV-B radiation particularly in the countries situated around the equator. Therefore, African populations have long been considered to have a low prevalence of vitamin D deficiency. Reliable, population-based data on vitamin D status in different African areas remain scarce as compared with other continents, but in the past 10 years, a considerable amount of studies have been published. The literature was recently reviewed in a meta-analysis [177]. A selection of studies from Africa is summarized in Table 54.6. In the meta-analysis, the estimated prevalence of 25(OH)D concentrations below 30 nmol/L is approximately

one in five people living in Africa, underlining that even in the sunniest continent, deficient vitamin D status is common. However, large variation in vitamin D status is present. Vitamin D deficiency is particularly common in populations living in northern African countries or South Africa compared with sub-Saharan Africa. For example, the mean 25(OH)D concentration from studies in Morocco is 44.5 nmol/L, whereas in countries around the equator such as Kenya or Uganda, mean concentrations are around 70–80 nmol/L [177–179,191,195]. In South Africa, 25(OH)D concentrations below 50 nmol/L are particularly common in specific populations such as Africans from Asian Indian origin, newborns, and pregnant women [177,197,198,201].

**FIGURE 54.3** Prevalence of vitamin D deficiency (serum 25-hydroxyvitamin D < 25 nmol/L) in different ethnicities in the Netherlands. Data from Van der Meer et al. [115].

**TABLE 54.4** Vitamin D status and prevalence of vitamin D deficiency in Middle East countries according to different studies.

### 3.7 Vitamin D status in Oceania

A selection of studies in Oceania, i.e., Australia, Pacific Islands, and New Zealand, is reported in Table 54.7. Latitudes in these studies range from 10° to 45°S. Although most countries in Oceania have a very sunny climate, a serum 25(OH)D concentration below 50 nmol/L is very prevalent, especially in pregnant Aboriginal women (56%) [205], community-dwelling men aged 70 years or over (43%) [209] and community-dwelling adults aged 50–80 years living in Tasmania (49%) [217], refugee children living in Sydney, Australia (61%) [210], and Northeast-Asian immigrants living in Canberra, Australia (68.8% in age group 30–39 years) [214]. Furthermore, low serum 25(OH)D concentrations (<50 nmol/L) were reported during early pregnancy (55%) [215], but less so in pregnant non-Aboriginal women in another study (20%) [205].

### 4. Multicenter and global studies using a central laboratory facility

Some studies have involved many countries or even several continents using one central laboratory facility. The advantage of these studies is that different assays for serum 25(OH)D and different laboratories are excluded as a source of variation. This is a great advantage because, as noted earlier, interlaboratory variation may be as high as 25% [7]. The Euronut Seneca study was done in older persons in European countries from the Mediterranean to Northern Europe [220]. In this study, there was a positive correlation between serum 25(OH)D and latitude, i.e., higher values in northern countries, the inverse of what was expected by sunlight exposure. This was confirmed by the baseline data of the MORE study, a study on the effect of raloxifene (a selective estrogen receptor modulator or SERM) versus placebo in postmenopausal women with osteoporosis [221], and baseline data of the randomized clinical trial with the SERM bazedoxifene [222]. In the latter (bazedoxifene) study, the correlation between serum 25(OH)D and latitude in other continents was negative as should be expected. The baseline data of the bazedoxifene study showed also a relationship between serum 25(OH)D and affluence with lower 25(OH)D levels in Eastern Europe than in Western and Northern Europe. The MORE study, the bazedoxifene study, and another global study [221–223] were all done in postmenopausal women with osteoporosis. Vitamin D status in these studies usually was better than in other studies because women participating in clinical trials usually are more concerned about their health. These three studies show a very poor vitamin D status in Middle Eastern countries confirming the data of national studies. Recently, values

from different European countries were standardized by the ODIN study [11]. The studies included in the European ODIN study usually are nationally representative and therefore a better estimate of the actual situation at least in Europe.

## 5. Ethnicity/migration

A recent review on vitamin D status in non-Western immigrants and refugees showed that vitamin D deficiency is common in this population [224]. Vitamin D status in immigrants from non-Western countries was poor in North America, Norway, the Netherlands, and Australia [21,114–116,225,226]. A review on this subject concluded that serum 25(OH)D in non-Western immigrants in the Netherlands was much lower than in those born in the Netherlands and was also lower than in people in their country of origin [227].

## 6. Nutrition

In Europe, a north–south gradient was observed for serum 25(OH)D with higher levels in Scandinavia and lower levels in Southern and Eastern European countries [220,221]. This indicates that other determinants than sunshine are of importance, e.g., nutrition, food fortification, and supplement use. Fortification of dairy products is practiced in the United States where vitamin D 400 IU is added per quart of milk. Fortification of milk is now also practiced in Sweden, Finland, and Ireland and resulted in a large improvement in vitamin D status in Finland [88].

## 7. Risk groups

Vitamin D deficiency is very common in certain risk groups, such as children with low birth weight (premature and small for gestational age), pregnant women, older people, and non-Western immigrants. Vitamin D status can be poor in adolescents as is seen in studies in Europe, the Middle East, and Asia [11,91,113,131,228,229]. Pregnant women, especially non-Western pregnant women and their children, are at high risk of vitamin D deficiency [116]. The dermal synthesis of vitamin D decreases with age, and especially older nursing home residents who do not come outside frequently are at high risk. Non-Western immigrants migrating to countries at higher latitudes with limited UV-B irradiation are at high risk because of more pigmented skin, the habit to stay out of the sun, the wearing of well-covering clothes, and a diet low in dairy products [114–116,226,227].

## 8. Trends in vitamin D status

General attention for widespread vitamin D deficiency may lead to recommendations for vitamin D supplementation and public health measures such as food fortification with vitamin D to improve vitamin D status [88]. On the other side, fear of skin cancer may increase the use of sunscreen, which may decrease vitamin D production in the skin [55]. Positive or negative trends in vitamin D status can only be reliably diagnosed when the measurement of serum 25(OH)D is free from bias. When two population samples with an interval of 5 or 10 years are compared, the serum 25(OH)D values should be made comparable by cross-calibration, using a gold standard assay, such as LC-MS, and DEQAS or preferably VDSP [11,14].

Trends were studied in the NHANES population study using LC-MS calibrated to a standard reference [56]. Serum 25(OH)D did not change between 1988 and 2006, but it increased 5–11 nmol/L between 2007 and 2010, the highest increase being observed in older white women probably due to supplement use. This was confirmed in the Study of Women's Health Across the Nation [57]. A negative trend was seen in Canadian children, probably due to decreased fish and milk consumption [58]. A negative trend was also seen in the Inuit population of Greenland between 1987 and 2005 [59,60]. Vitamin D insufficiency (serum 25(OH)D < 50 nmol/L) was observed in 77% of young adults. The decrease was attributed to the change of traditional diet of fish and sea mammals to a Western diet.

In the United Kingdom, an increase in the prevalence of rickets was seen in hospital discharge data [61]. Conversely, the free distribution of vitamin D3 400 IU/d to infants in Turkey led to the almost disappearance of rickets in infants and toddlers in a few years [118]. A very positive trend in vitamin D status was observed in Finland after the fortification of milk and yogurt with vitamin D3 400 IU/L [88]. Mean serum 25(OH)D increased 17 nmol/L between 2000 and 2011, and the prevalence of vitamin D deficiency decreased from 59% to 14%. Positive trends in vitamin D status were also observed in Lebanon and Iran [62,63]. These positive trends were attributed to more awareness, more screening, and more supplementation. A similar positive trend was observed in India, where the analysis of serum samples in a large hospital showed an increase of mean serum 25(OH)D and a decrease of vitamin D deficiency [64]. On the other side, a very significant decrease of vitamin D status was seen in South Korea between 2008 and 2014. Mean serum 25(OH)D decreased 10 nmol/L in men and 7 nmol/L in women [65]. The decrease was attributed to urbanization, air pollution, and less outdoor activity.

In conclusion, positive trends can be observed, mainly with vitamin D supplementation and food fortification, while negative trends are the consequence of dietary changes and less sun exposure.

## 9. Implications

Vitamin D deficiency has been classically associated with mineralization defects, bone loss, osteoporosis, and fractures [66,222] (see Chapters 62 and 63). The causal relationship between vitamin D deficiency and fractures has been confirmed by randomized clinical trials [67]. Vitamin D deficiency has also been linked to muscular weakness, decreased physical performance, and falls [68–70]. The latter relationship has also been confirmed by clinical trials [71]. In recent years, vitamin D deficiency has been associated with nonclassical outcomes, such as cardiovascular disease, diabetes mellitus, multiple sclerosis, tuberculosis, respiratory infections, and several types of cancer [72]. However, for all of these nonclassical outcomes, many clinical trials have been negative, and causality has not been established. The magnitude of the negative health effects attributed to vitamin D deficiency also depends on the percentage of the population having a low vitamin D status. Roughly 50% of the Western–European population has a serum 25(OH)D concentrations below 50 nmol/L at least in winter. This percentage is lower in North America and appears higher in South America. The prevalence of vitamin D deficiency is higher in Northern African countries and South Africa than in sub-Saharan Africa. Vitamin D deficiency is around 50% in Oceania. Studies from the Middle East and Asia reveal severe vitamin D deficiency in the Middle East, China, Mongolia, and India. It is important to do more research in these countries, especially in Asia, where a relatively large part of the world population lives.

In summary, to be able to estimate the burden of vitamin D deficiency, more prevalence studies are needed in Eastern Europe, the Middle East, Asia, Africa, and some South American countries. Quality control of the serum 25(OH)D assays should be done at least by participation in a quality assurance scheme such as DEQAS [8], and the % deviation from the overall mean should be reported. Preferably, results should be standardized by participating in a program such as VDSP [11].

Prevention requires moderate sunlight exposure, consumption of fish, fortification of foods with vitamin D, and the use of vitamin D supplements. A supplement of vitamin D3 400 IU/d can be recommended for children and also for adults who do not come outside or have a dark skin. Pregnant and lactating women may require 400–800 IU per day. Older persons also require

a supplement of 400–800 IU per day, the higher dose with insufficient sun exposure or dark skin. Patients with osteoporosis and older persons in rest or nursing homes require 800 IU per day. It will require an enormous effort to bring up serum 25(OH)D levels to more than 50 nmol/L in all continents all year long.

## 10. Conclusions

Vitamin D deficiency (serum 25(OH)D < 25 nmol/L) and low vitamin D status (serum 25(OH)D < 50 nmol/L) are very common in most countries around the world. Severe vitamin D deficiency is common in the Middle East, China, Mongolia, and India. Risk groups are children, especially those with low birth weight, adolescents, pregnant women, older persons, and non-Western immigrants. Probably less than 50% of the world population has an adequate vitamin D status (serum 25(OH)D > 50 nmol/L) at least in winter. Prevention requires moderate sun exposure, consumption of fish, fortification of foods, and the use of vitamin D supplements.

## 11. Summary points

- Vitamin D deficiency and low vitamin D status are very common in most countries around the world.
- More prevalence studies are needed in Eastern Europe, the Middle East, Asia, Africa, and some South American countries.
- Studies should participate in a quality control program such as VDSP to make prevalence rates comparable.
- Vitamin D deficiency (25(OH)D < 25 nmol/L) and low vitamin D status (serum 25(OH)D < 50 nmol/L) can be prevented by moderate sun exposure, consumption of oily fish, fortification of foods with vitamin D, and use of vitamin D supplements.

# Vitamin D in food—Compounds, stability, sources

Jette Jakobsen and Marie Bagge Jensen

Technical University of Denmark, Kgs. Lyngby, Denmark

## OBJECTIVES

- Describe the chemistry of vitamin D—provitamins and vitamers.
- Describe the chemical changes of vitamin D due to physical factors such as light, temperature, pH, and oxygenation.
- Outline the analysis of vitamin D in food.
- Describe the distribution of vitamin D in foods in nature (natural content).
- Discuss the effects of production facilities on vitamin D content in primary food.
- Discuss the chemical changes in vitamin D during food processing (retention).
- Detail the content of vitamin D in food as documented in databases.
- Discuss the calculation of dietary intake of vitamin D.

## 1. Introduction

Even though vitamin D is not a vitamin for all humans, as it depends on whether we have access to sun or not, the content in our food is essential. The recommendation for daily dietary intake of vitamin D is set to 10–20 µg/day [1–3]. Information on the food types in our diet will enable estimation if the dietary intake meets, or to what extent meets, the daily dietary recommendation for vitamin D.

One of the great scientists Sir Lord Kelvin said: “When you can measure what you are speaking about and express it in numbers, you know something about it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind.” This statement somehow makes sense for vitamin D in food. The discovery and elucidation of the understanding of the physiological mechanism of vitamin D are linked to the history of analytical chemistry, and this explains why it took 50 years to discover the active vitamin D forms, and why some of our knowledge of content of vitamin D in food is still limited.

Cod liver oil was part of the discovery of vitamin D [4]. This was followed by investigation of the effect of sunlight on baby chicken and pigs [5,6], as well as sunlight and artificial light on cows and milk [7,8]. The irradiation resulted in a positive outcome for the animal husbandry and the food produce, which enabled the statement in 1925: “the time is probably not far distant when every producer of high grade milk will find it necessary to irradiate his cows artificially” [7]. The researchers observed a positive effect in curing rickets, but did not have the tools (analytical methods), to estimate changes in vitamin D. In the 1920–1960s, the analytical tools to understand vitamin D in food or as a pure compound were limited to biological methods, which could estimate the vitamin D content by their effect in curing rickets in animals, or spectrophotometric changes to evaluate the effect of exposure of light [9–11].

A lot of effort has been put into understanding the degradation of vitamin D (crystals or in solution). The knowledge of the effect of physical factors like light, temperature, pH, and oxidation on vitamin D, was mainly established before 1980. In the 1970s, the breakthrough of liquid chromatography eventually enabled

the development of methods, which could quantify the level of vitamin D ( $\mu\text{g}/100\text{ g food}$ ) [12,13]. Then in the 1990s the principle for the method, which is used today, was introduced and the content in foods on the market (in Finland) of the specific vitamin D vitamers was stated [14]. Vitamin D is presented in food in an amount of  $\mu\text{g}/100\text{ g food}$  [15]. Statements of where to find vitamin D in our food usually include fatty fish, eggs, organs, and meat, and if available, fortified food, but neglects the information that vitamin D stability is sensitive to oxygen and light.

The aim of this chapter is to describe the physical factors that induce vitamin D degradation; the analytical methods used to quantify vitamin D in foods; natural, current, and potentially future content in foods; the effect of storage and processing; quantification of total vitamin D activity; challenges of using food composition data; and then consider the prospects for future research.

## 2. Chemical structure of vitamin D vitamers

### 2.1 Which chemical structures have vitamin D activity?

The provitamin D, i.e., the sterols, 7-dehydrocholesterol (7DHC), and ergosterol, has the steroid form (ring A, B, C, D), see Fig. 55.1. The vitamin D compounds are a family of 9,10-secosteroids, which for the parent form differ only in side-chain structure. Compared to sterols, secosteroid has an open ring, which for vitamin D is the B-ring. The difference between the primary vitamin D compounds, cholecalciferol (vitamin D<sub>3</sub>) and ergocalciferol (vitamin D<sub>2</sub>) is a double-bound in the side chain between carbon 22 and carbon 23, and the extra methyl group at carbon 24,

see Fig. 55.1. The intermediate previtamin D is a 6,7-cis isomer form and isomerize in a temperature-dependent equilibration to vitamin D [16,17]. In animal products, the vitamin D vitamers 25-hydroxyvitamin D (25(OH)D) and 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D) are present due to the metabolism in vertebrates i.e., 25-hydroxylation and 1 $\alpha$ -hydroxylation primarily in the liver and the kidneys (see Chapters 4, 8 and 9) [18].

Besides vitamin D<sub>2</sub> and vitamin D<sub>3</sub> other parental forms of vitamin D vitamers are vitamin D<sub>4</sub> to vitamin D<sub>7</sub>, see Table 55.1. However, the interest of these vitamers in food is limited, due to their insignificant biological activity, which has been investigated for vitamin D<sub>4</sub> and vitamin D<sub>5</sub> [19–21]. Similarly, the dihydroxylated metabolites e.g., 1,25(OH)<sub>2</sub>D and epimers of 25(OH)D will in general not be covered.

## 3. Stability of vitamin D

### 3.1 What can happen to the antirachitic compounds vitamin D<sub>2</sub> and vitamin D<sub>3</sub> in crystal form and when dissolved in organic solvents?

Knowledge of the stability of vitamin D is especially important to take into consideration when analyzing (extraction and sample clean-up), quantifying vitamin D in different matrixes, and when storing samples and standards. These processes are further important to comprehend to understand and avoid the degradation of vitamin D during food processing and storage.

Vitamin D was differentiated from vitamin A as cholecalciferol is more heat stable and resistance to oxidation. The observation was that cod liver oil heated (120°C) and aerated for 12 h still has the ability to cure rickets, while not able to cure xerophthalmia in rats

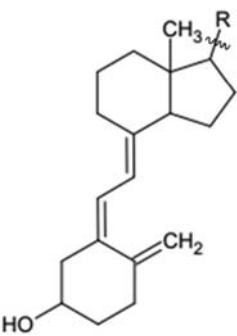

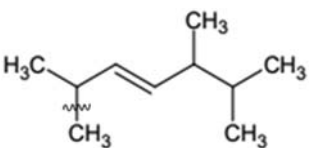

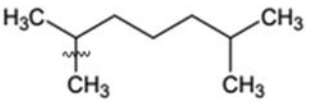

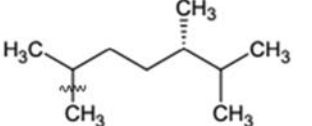

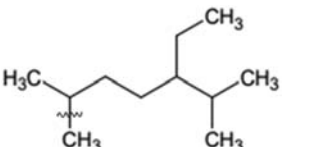

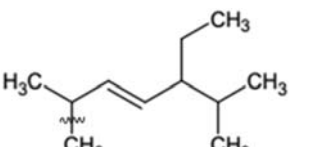

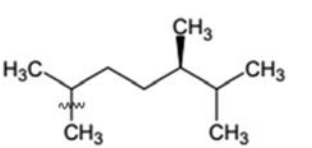

FIGURE 55.1 Metabolism of vitamin D in vertebrates.

TABLE 55.1 Structure of the different vitamin D vitamers with their specific provitamins.

	R	Vitamin D	Provitamin
		D2	Ergosterol
		D3	7-Dehydrocholesterol
		D4	22,23-Dihydroergosterol
		D5	7-Dehydrositosterol
		D6	7-Dehydrostigmasterol
		D7	7-Dehydrocampesterol

[4]. Studies into the synthesis, stability, and analyses of vitamin D have identified the physical factors and the degradation products from exposure to light (different wavelength), temperature, pH, and oxidation.

### 3.2 Exposure to light

Ergocalciferol (vitamin D<sub>2</sub>) and cholecalciferol (vitamin D<sub>3</sub>) are produced by UVB-exposure to ergosterol and 7DHC [22,23]. Further exposure of ergocalciferol by 247 nm up to 290 nm in ethanol and of crystals showed loss of antirackitic effect [24]. The compounds identified were toxisterols generated from previtamin D and suprasterol I and II from vitamin D [25,26], see Fig. 55.2A. Sunlight exposure of vitamin D<sub>3</sub> in methanol revealed formation besides suprasterol I and II, also 5,6-trans vitamin D<sub>3</sub> [27]. Thirteen toxisterols have been isolated, and the structure of compounds depends on the solvent in which they are formed e.g., alcohol or ether [25]. Vitamin D chromophore cause

the absorption of light in the same wavelength as provitamin D (7DHC) and previtamin D. Thus the photochemical transformation of these compounds takes place under the same environmental condition (wavelength of light exposure) [28].

Crystals of vitamin D<sub>2</sub> degrade in amber glasses, but to a lesser extent than in ordinary glasses [11]. A solution of vitamin D<sub>3</sub> in acetonitrile showed no degradation by indoor light (fluorescent lamp F15T8/CW) for 10 days [29]. Solutions of vitamin D<sub>3</sub>, vitamin D<sub>2</sub>, and 25(OH) D<sub>3</sub> in ethanol in clear, glass vials stored either in dark for 7 days, exposed to light (no UVB and UVA) for 7 days, or exposed to UVB for 7 days, showed significant degradation when exposed to UVB ( $P < .01$ ) for all three vitamers (Jakobsen, personal communication).

### 3.3 Thermal treatment

Thermal degradation was shown for ergocalciferol at temperatures above 150°C during distillation, and

**FIGURE 55.2** Vitamin D isomerization products formed by UVB-exposure (A), \* identified following sunlight exposure; thermal treatment above 150°C (B); acid (C), the primary product at low temperature; oxidation/singlet oxygen (D). Exemplified by vitamin D<sub>3</sub>.

the resulting compound was termed pyrocalciferol [23,24], while isopyrocalciferol was designated at a later stage [30,31]. Heating experiments of cholecalciferol identified the thermal products to derive from the precholecalciferol [32]. See Fig. 55.2B. Heating cholecalciferol in different solvents found the thermal isomers formed from 100 to 170°C, while in a model system the degradation is estimated to start at 156°C and 166°C for vitamin D<sub>3</sub> and vitamin D<sub>2</sub>, respectively [32,33].

### 3.4 Treatment at different pH

Treatment of vitamin D by acid results in the isomerization of previtamin D to primary isotachysterol and some isocalciferol, and the isomerization rate depended on acidity [34]. Acid isomerization of vitamin D<sub>3</sub> in methanol in the dark at ambient temperature produce isotachysterol, but also seven oxygenation products in a self-initiated autoxidation reaction [35]. However, only isotachysterol is formed at low temperature (0°C), in the dark, and under inert gases such as nitrogen. This procedure was applied in a gas chromatographic method [36]. See Fig. 55.2C. The stability toward alkaline pH was not essential until alkaline saponification (15% KOH in methanol) was investigated as a procedure to remove fat from the vitamin D matrix. High pH did

not cause any degradation of vitamin D<sub>3</sub>, which was used for the analyses of vitamin D by liquid chromatography [37].

### 3.5 Oxidants and singlet oxygen

In the presence of the oxidant iodine previtamin D isomerizes to 5,6 trans previtamin D (tachysterol), while vitamin D isomerizes to 5,6 trans vitamin D. See Fig. 55.2D. The higher temperature the equilibrium between previtamin D<sub>3</sub> ↔ vitamin D<sub>3</sub> is favorable for previtamin D<sub>3</sub>. Thus at room temperature 5,6 trans vitamin D is formed, and at temperatures such as 70°C, also tachysterol [31,38].

Vitamin D<sub>3</sub> in a solution of methanol and acetonitrile and exposed to a stream of oxygen or air showed degradation within 1.5 h and over a period of 10 days [29,37].

The singlet oxidation of the conjugated triene part of vitamin D<sub>3</sub> was initially generated by sodium hypochlorite-hydrogen peroxide in a vitamin D<sub>3</sub> solution [39]. Vitamin D oxidation with singlet oxygen formed vitamin D epoxides [40,41]. Riboflavin, a water-soluble vitamin, is an excellent photosensitizer if exposed to light. In a solution with vitamin D and exposed to light, riboflavin produced singlet oxygen, which oxidized vitamin D. The oxidation of vitamin D

did not occur if not light exposed [42]. One of the compounds formed is 5,6-epoxide of vitamin D [43]. See Fig. 55.2D.

### 3.6 Solvents and vitamin D

Crystal powder of vitamin D<sub>3</sub> could be stored under nitrogen or in vacuum at 25°C for up to 56 days, while vitamin D<sub>2</sub> in vacuum start degrading after 7 days [44]. The stability of vitamin D at lower temperatures depends on its solvent e.g., vitamin D<sub>2</sub> and vitamin D<sub>3</sub> are stable for up to 36 months in propylenglycol and amber vial, without replacement of air [45]. In isooctane or ethanol in vacuum or under nitrogen revealed that no loss was observed in ethanol, but loss appeared in isooctane [37]. The stability of vitamin D<sub>3</sub> in acetonitrile at 4°C versus 21°C for a period of 10 days, was significantly affected by temperature, with significantly higher stability at 4°C [29]. Storage at –20°C for crystals and in ethanol or n-heptane for a minimum of 2 years can be done without any significant degradation of vitamin D vitamers (Jakobsen, personal communication). Table 55.2 sums up the environmental factors, which cause vitamin D to become unstable or stable as crystals or in solution.

## 4. Analytical methodology

### 4.1 Principle for the extraction, detection, and quantification of vitamin D (vitamin D<sub>3</sub>, 25(OH)D<sub>3</sub>, vitamin D<sub>2</sub>, and 25(OH)D<sub>2</sub>) in foods including LOQ, precision, and accuracy

Vitamin D is present in free form but exists also in other forms, for example as fatty acid esters [46,47]. Vitamin D is stable in an alkaline solution, and alkaline saponification is the preferred method for the degradation of fat in food samples. The analytical method to quantify vitamin D vitamers in food includes steps

similar to those introduced 50 years ago: alkaline saponification, followed by liquid-liquid extraction followed by a selection of clean-up steps, which depend on the final detection and quantification principle. For vitamin D in food, the standard methods for vitamin D [48] include a solid-phase extraction, semipreparative HPLC and/or thin layer chromatography, before the final detection by DAD/UV, and quantification by use of internal standard for vitamin D<sub>2</sub> for vitamin D<sub>3</sub> and vice versa. The original establishment of certified reference materials for the content of vitamin D revealed that the analyst needs to be skilled and ensure correct sampling in the preparative clean-up, a solvent suitable to dissolve the vitamin D, and a satisfactory baseline resolution in the final analytical chromatography [49]. The same principle was introduced for quantification of 25(OH)D [14]. The development of tandem mass spectrometry methods to quantify vitamin D and 25(OH)D in food diminished the number of clean-up steps to primarily alkaline saponification, liquid-liquid extraction, and an SPE-step before injecting the solution to the LC-MS/MS. The use of Diels-Adler derivatization step to form a vitamin D adduct which enhances the signal using electrospray ionization was initially introduced for analyses in plasma and then transferred to food [50,51]. This principle is used in the standard method for vitamin D in infant formula and adult nutritional [52], while no standard method is available for 25(OH)D either using DAD/UV-detection or tandem mass spectrometry.

Pitfalls in the analyses for vitamin D in food include the fact that deuterium labeled standards do not necessarily compensate for ion suppression or ion enhancement during ionization as the deuterated form elutes earlier, thus carbon labeled vitamin D standard should be prioritized [53]. Furthermore, the mandatory use of internal standards is caused by the equilibrium between previtamin D ↔ vitamin D [16]. In food, no difference appears between saponification at room temperature (20°C) and at high temperature e.g., 75°C [14,54].

**TABLE 55.2** condition leading to instability or stability of vitamin D<sup>a</sup>.

Factor	Vitamin D (crystals and pure solution)		Vitamin D in foods	
	Instable	Stable	Instable	Stable
Light	UVB	x (>UVA)	UVB (>content)	x (>UVA)
Temperature	>150°C	–20°C	>150°C	–20°C
PH	Acid	Neutral, alkaline	n.o.	Neutral, alkaline
Oxidation	X		X	
Singlet oxygen	X		x	

<sup>a</sup>Presence of water i.e., humidity/water activity accelerates loss.  
n.o. no observation.

However, in the analysis of fortified foods the analyst should be aware of the potential risk that internal standards do not fully correct for equilibrium. In this case, hot saponification should be prioritized [55].

The reliability of data for the content of vitamin D in foods is dependent primarily on documentation of trueness, precision, and the limit of quantification. Trueness describes the quantified level compared to other laboratory or referenced to certified reference material. The challenge for vitamin D research is the limited number of reference materials with certified values [56], and that a proficiency test is only available for vitamin D<sub>3</sub>. Precision describes the within laboratory repeatability and between laboratory repeatability (reproducibility) and is assessed during the standardization of a method, which for vitamin D<sub>3</sub> in food [48] is based on data from certification of e.g., fortified margarine showing 6.5% and 8.4%, respectively [49]. The validation of the LC-MS/MS standardized method for infant formula and adult nutritional included eight laboratories, which used the standardized method description in the analyzes of samples (0.7–14 µg vitamin D<sub>3</sub>/100 g). The repeatability and reproducibility obtained were max. 5.8% and 12.7%, respectively [52]. No standardized method is available for 25(OH)D<sub>3</sub> in food, but to provide an idea of the precision for this vitamin the results from a laboratory comparison (five laboratory using own in-house LC-MS/MS methods) analyzed samples containing >0.1 µg/100g. Repeatability and reproducibility were for vitamin D<sub>3</sub> max. 9.7% and 14.8%, respectively, and for 25(OH)D<sub>3</sub> max. 16% and 24%, respectively [57]. It is expected that at lower levels a higher repeatability and reproducibility is observed, especially if no optimization was done beforehand [49].

The capability of an analytical method is also described by the limit of quantification (LOQ), which is essential for vitamin D. The method chosen should fulfill the criteria for the lowest content of interest. If values are intended for food databases, the LOQ preferable should be defined based on the expected dietary intake. The optimal analysis will be that which is performed accredited according to ISO17025, which e.g., ensures the documentation of trueness and uncertainty. For the studies referred to in the next sections, the information on trueness is in the range 80%–120% and repeatability <10% [14,54,58–61]. Further details on vitamin D assay standardization in the analyses of serum/plasma are provided in Chapter 49.

In the description of analytical methods, biological methods used for the analysis of food were by choice omitted. Thus, in the forthcoming section only data derived from specific, chemical methods are included. In the investigation of cause and effect, repetition is essential, and studies are only included if a minimum

of three replicates and precision are available or can be calculated from data in the original paper.

## 5. Vitamin D in food

Generally, only foods of animal origin contain vitamin D, and from the early history of vitamin D research, it was observed that sunlight has an enormous effect on the produce of antirachitic compounds. Thus, the vitamin D content of animal products is controlled by biological metabolism and may vary with the amount of vitamin D in animal feed, access to pasture, season, and between animal species. The majority of animal husbandry involves living indoors. In this section only results reported from free-living animals are reported while the content in farmed animals/aqua-cultured fish is reported separately—and in combination with the possibility for biofortification. All content is presented as µg/100 g fresh weight. Recalculation from IU to µg by multiplication 0.025 has been done. If data is presented per g dry matter (DM) value was recalculated to per g fresh weight, and if % DM is not presented the assumption of the content of % DM is indicated in each case.

### 5.1 Vitamin D in food from wild fish and animal

The natural level of vitamin D in fish and animals is difficult to define and assess, partly because specific data is lacking due to the analytical challenges, and partly because the specification of the analyzed sample not necessarily is reported. For example, salmon may be a *Salmo salar* or a *Onchorhynchus* sp. The specific challenges will be discussed for each of the possible vitamin D sources, including fish, egg, meat, organ, mushroom, plants, and insects.

It was noted that fish liver oils contained varying amounts of vitamin D, up to 112,500 µg/100 g from oriental tuna, 17,500 µg/100 g from swordfish, 3000 µg/100 g from halibut, and 2500 µg/100 g from Atlantic cod [9]. By exception, these values are based on the biological method, but similar high values or even higher were reported by a chemical method e.g., halibut liver oil at 9200–13,000 µg vitamin D/100 g and in cod liver oil 8800 µg vitamin D<sub>3</sub>/100 g [13]. Similarly, huge variation of vitamin D in flesh from wild-caught fish species has been shown in the range of 1–27 µg vitamin D<sub>3</sub>/100 g [58,62]. The content of vitamin D is not correlated to the content of fat, age, weight or sex, but an effect of habitat has been shown [58,62–64]. Atlantic salmon (*Salmo salar*) when caught in the Baltic Sea is reported to have a content of 18.5–26.5 µg vitamin D<sub>3</sub>/100 g, if caught in the North Sea/Atlantic Ocean the content is

reported to 8.4–9.4  $\mu\text{g}$  vitamin D<sub>3</sub>/100 g [58,63,65]. Wild salmon caught in the Pacific Ocean (*Onchorhynchus* sp) shows a content of 14.2  $\mu\text{g}$  vitamin D<sub>3</sub>/100 g [66]. The variety of vitamin D in salmonids nicely demonstrates the huge variation which nature provides us. See Fig. 55.3, which shows the content of vitamin D and fat in selected fish species. Within a fish species, the sampling of herring and mackerel over a year shows the independence of vitamin D from levels of fat within a species, see Fig. 55.4.

In addition to the content of vitamin D in fish, the origin of vitamin D in fish has been investigated. In the early days of vitamin D research estimation of vitamin D in phyto- and zoo-plankton was hampered by sensitivity and specificity of the analytical method available. The conclusion was no vitamin D in phyto-plankton, but minor in zoo-plankton [67]. In the last 30 years, a few studies did report the natural level of zoo-plankton from lakes in Japan and in Finland, and from the Indian Ocean to approx. 0.015–2.7  $\mu\text{g}$  vitamin D<sub>3</sub>/100 g

(assuming 1% DM [64]) [64,68,69]. While the content of vitamin D<sub>3</sub> in phyto-plankton from a Japanese lake and the Indian Ocean contained approx. 0.22–8.0  $\mu\text{g}$  vitamin D<sub>3</sub>/100 g (assuming 10% DM) [68,69].

The natural level of vitamin D in eggs can be hypothesized to be the level in eggs from hens, which in a research project was provided for hens who had the possibility to stay outside for a period of 4 weeks in summertime (51°N). The content in these eggs was 4.5  $\mu\text{g}$  vitamin D<sub>3</sub>/100 g and 1.3  $\mu\text{g}$  25(OH)D<sub>3</sub>/100 g [70].

In contrast to hens, dairy cows have often access to pasture, and dairy cows delivering organic milk, they have access to pasture from spring to autumn. For dairy cows sun-exposed during summer in New Zealand (38°S) and in Denmark (55°N), the maximum content of vitamin D<sub>3</sub> in milk fat per 100 g was 0.58 and 0.53  $\mu\text{g}$  vitamin D<sub>3</sub>, respectively [61,71]. These levels indicate a level in fresh, whole milk (3.5% fat) of approx. 0.020  $\mu\text{g}$  vitamin D<sub>3</sub>/100 g, and 0.008  $\mu\text{g}$  25(OH)D<sub>3</sub>/100 g [71].

FIGURE 55.3 Content of vitamin D and fat in fish species from natural habitats [58,64,65,89,145].

FIGURE 55.4 Content of vitamin D and fat in tuna, mackerel, and in herring wild caught.

For meat, the content of vitamin D in beef cattle on pasture in Queensland, Australia (17°S) indicates in minced beef (10% fat) a content of 0.24 µg vitamin D<sub>3</sub>/100 g and 0.11 µg 25(OH)D<sub>3</sub>/100 g [72]. For pork, the content of vitamin D from free-range pigs, which have mandatory access to outdoor areas in Denmark (55°N), showed a content of 0.88 µg vitamin D<sub>3</sub> and 0.38 µg 25(OH)D<sub>3</sub> per 100 g lean meat (4.2% fat) [73].

Wild-grown mushrooms in Sweden and Finland had a content of 10.7–29.8 µg vitamin D<sub>2</sub>/100 g *Cantharellus* and 2.9–58.7 µg vitamin D<sub>2</sub>/100 g *Boletus Edulis* [74,75], while analyses of wild grown white button mushroom (*Agaricus Sp.*) from Denmark and Finland did reveal content of 0.2–1.5 µg vitamin D<sub>2</sub>/100 g [75,76]. Otherwise, the knowledge of vitamin D in plants is limited, but in edible vegetables vitamin D<sub>3</sub> is not present [77]. Even though lichen is not a foodstuff for humans, it should be mentioned that this symbiotic organism, which consists of a fungus and an alga, has been found to contain vitamin D<sub>3</sub> in an amount of 2.3–4.7 µg per 100 g (assuming 10% DM) [78]. Future sustainability goals may include insects in the diet, which are reported to contain <0.01 µg vitamin D<sub>3</sub>/100 g (assuming 10% DM) [79].

## 5.2 Vitamin D in food farmed by man-fish, eggs, milk, meat (pork/beef/chicken), mushrooms, and plants

What are the levels of vitamin D in marketed food products, and what levels have been reported in research facilities? First of all, data in food composition tables are intended to provide the best estimate for the content of food on the market in the difference areas/countries of the world (<https://www.fao.org/infoods/infoods/tables-and-databases/faoinfoods-databases/en/>). However, few of these databases specify the individual content of vitamin D vitamers and published data for these individual results are limited, mainly due to the high cost of vitamin D analyses, and the relatively short time-frame in which analytical methods have been available. Thus, this section highlights the published results, which have reported the content of individual vitamin D vitamers, and preferably that the sampling is representative of the region the data are intended for. Furthermore, the absent of fat content has been an acceptance criterion, in order to make the most appropriate comparison between studies. Even though in fish, no correlation between fat and vitamin D in fish species has been observed [62], fat-soluble vitamins have been reported to be associated with content of fat in pork, milk, and beef [71,72,80].

Cod liver oil is marketed as a supplement to diet e.g., with a content of approx. 200 µg vitamin D<sub>3</sub>/100 mL [13], which is far lower than reported for unprocessed

products [9,13]. The reports for vitamin D collected for food databases in aqua-cultured salmonids, *Salmon salar*, state content of 5.9 (2.3–8.2) µg vitamin D<sub>3</sub>/100 g, and for *O. Mykiss* 7.0 µg vitamin D<sub>3</sub>/100g [81–83]. These levels are lower than reported above for wild-caught *Salmo salar*. See Fig. 55.5. Though feeding trials in *Salmo salar* have shown an effect on the content of vitamin D in flesh by increasing vitamin D in the feed, the enhancement differs [63,84]. One study showed an increase to 9.5 µg vitamin D<sub>3</sub>/100 g using approx. 1500 µg vitamin D<sub>3</sub>/kg feed, while the other obtained content of 35 µg vitamin D<sub>3</sub>/100 g by feeding 3500 µg vitamin D<sub>3</sub>/kg feed. It is hypothesized that the effect of feeding could be strain-specific, which has been observed for salmon in a growth experiment [63,85]. A similar feeding experiment in *O. mykiss* showed no effect on vitamin D in the flesh of increased vitamin D in the feed [86]. In 2019 in the EU, the content of vitamin D in fish feed was regulated, and for salmonids increased from a maximum level of 75 µg/kg feed to 1500 µg/kg feed [87]. The effect of this on salmon vitamin D levels will be followed in future studies, but by 2022, vitamin D in salmon in the Danish market had not increased (Jakobsen, personal communication). Another aqua-cultured species is Tilapia, which is reported to contain 20–40 µg vitamin D<sub>3</sub>/100 g [88,89], while the seawater aqua-cultured species Giant sea perch and Short-bodied mackerel contained 3 µg/100 g [89]. The content of vitamin D<sub>3</sub> is included, as the other vitamers are insignificant in wild-caught fish, though aqua-cultured salmon contains 25(OH)D<sub>3</sub> in an amount of approx. 10%–20% of vitamin D<sub>3</sub> [90].

The capability of fish to synthesize vitamin D on exposure to ultraviolet UVB-light (300 nm) was examined in the freshwater fish tilapia (*Tilapia mossambica*) and resulted in a significant increase of vitamin D<sub>3</sub>. The content of vitamin D increases from 4 µg/100 g to 20 µg/100 g when the fish was exposed to UVB-light [91]. The UVB-light at 300 nm can travel through to a depth of 20 m in the sea [92]. Thus, UVB-light does travel through water, and especially the fish species living in the limnetic zone, including swordfish, tilapia, and silver barb, may gain vitamin D from this route. Otherwise, it is hypothesized that the vitamin D in consumed plant- and zooplankton is the main source of vitamin D for fish [69]. Regarding exposure to blue light on the skin of trout (*O. mykiss*), one group reported production of vitamin D by using blue light 380–480 nm, while another group did not see any vitamin D production by using light at 410–500 nm on the skin of Atlantic salmon (*S. salar*) [93,94].

In general, eggs (cage or free-range) are a good source of vitamin D. The reported result from three food data bases are in average between 0.6 and 2.5 µg vitamin D<sub>3</sub>/100 g and 0.13–1.0 µg 25(OH)D<sub>3</sub>/100 g [73,95,96].

**FIGURE 55.5** Content of vitamin D and fat in raw, salmonids—wild caught and aqua-cultured [58,63,65,81,145].

For these values, no information on the vitamin D content in the feed is available. A linear dependence of vitamin D in egg to vitamin D in the feed up to a maximum 620 µg/kg feed, provide the possibility to produce eggs that contain 61 µg vitamin D<sub>3</sub>/100 g without harmful effect for either hens or egg strength [97]. The possibility to manipulate the content of vitamin D in eggs has been shown through feeding and by UVB-exposure [2,60,97–99]. The maximum approved level of vitamin D<sub>3</sub> in the EU is 80 µg/kg feed, which is estimated to give 2.1 µg vitamin D<sub>3</sub>/100 g egg and 0.5 µg 25(OH)D<sub>3</sub>/100 g egg. Another possibility is to use 25(OH)D<sub>3</sub> as vitamin D source in the feed, which will increase the content of 25(OH)D<sub>3</sub> in the egg, but not in a linear relationship, and result in a minor increase of vitamin D<sub>3</sub> in the egg [97]. UVB-light in chickens facilities could, within 6 weeks of exposure of the legs of the hens, increase vitamin D content fourfold, which approximately resulted in a content in the eggs of 6.3 µg vitamin D<sub>3</sub>/100 g and 0.9 µg 25(OH)D<sub>3</sub>/100 g [100]. An alternative biofortification strategy is UVB-exposure of egg yolk, which also shows an increase in the content of vitamin D<sub>3</sub> due to the presence of 7-DHC [97].

Studies conducted for food databases show content of vitamin D in the milk of 0.26 µg vitamin D<sub>3</sub>/100 g milk

fat [73]. If an 85% retention during pasteurization is assumed (see below), the content is estimated to 53% of the “natural” level (see above). When feed containing the recommended level of approx. 7 µg vitamin D/kg feed (assumption 70 kg feed/day) was utilized, and no omission of a winter decline of vitamin D in conventionally produced milk was observed [71]. In the EU the approved max. is 100 µg vitamin D/kg feed [101], which could enhance the content in the milk during winter-time. Cows are very efficient in producing vitamin D in their skin by sun-exposure, and sun-exposure will cause the production of vitamin D in all parts of the cows [102]. Thus an alternative is the use of UVB-exposure in indoor dairies, which has shown an increase of vitamin D to “natural” levels in milk [103]. Furthermore, the applicability of UVB-treatment of milk was used in the 1940’s to enhance the content of vitamin D in milk, and the process is approved in the EU [104].

### 5.2.1 Pork

In Denmark, the levels of vitamin D in conventional pork (4.2% fat) are, on average, 0.052 µg vitamin D<sub>3</sub>/100 g and 0.050 µg 25(OH)D<sub>3</sub>/100 g [105], while reported content in lean meat of cuts from Canada is 0.14 µg vitamin D<sub>3</sub>/100 g and 0.09 µg 25(OH)D<sub>3</sub>/100 g [88]. These values indicate that farmers in the two

countries may use different levels of vitamin D in pig feed. Pigs in conventional farming are raised indoors, and thus the level of vitamin D in pork products depends on the content of vitamin D in the feed and/or the source, which can be either vitamin D<sub>3</sub>, 25(OH)D<sub>3</sub>, or vitamin D<sub>2</sub> [106,107]. Trials in pigs fed with the maximum allowed level (in the EU at 50 µg/kg feed) of vitamin D<sub>3</sub> showed a vitamin D content in pork (2.2%–2.1% fat) at max. 0.14 µg vitamin D<sub>3</sub>/100 g and 0.19 25(OH)D<sub>3</sub>/100 g [106,107]. In research facilities, UVB-exposure has been used in indoor stables for pigs, which by exposure for 4 weeks achieve content in pork (1.5% fat) at 0.37 µg vitamin D<sub>3</sub> and 0.24 µg 25(OH)D<sub>3</sub> per 100 g [108]. These contents are higher than by feeding, and minced pork (10% fat) could provide the consumer in 100 g with 1.7 µg vitamin D<sub>3</sub> and 0.3 µg 25(OH)D<sub>3</sub>. The content in the rind of UVB-exposed pigs was even higher at 31.6 µg vitamin D<sub>3</sub>/100 g.

Similar to the enhancement of the content of vitamin D in egg-yolk and milk, UVB-exposure to pork rind may enhance the content of vitamin D. The content of 7DHC in processed pork rind (pork crackling), can be used to produce cracklings with tailored content of vitamin D e.g., 10 or 20 µg/100 g by UVB-exposure [109]. Interestingly drinking water with ultrahigh content of vitamin D<sub>3</sub> (2.8 mg/100 mL) during lairage time prior to slaughter improved the tenderness of the meat [110].

### 5.2.2 Chicken

Food composition data for minced chicken (7.5% fat) revealed 0.10 µg vitamin D<sub>3</sub>/100 g and 0.44 µg 25(OH)D<sub>3</sub>/100 g, while data from Finland (9.7% fat) showed 0.29 µg vitamin D<sub>3</sub>/100 g and 0.25 µg 25(OH)D<sub>3</sub>/100 g, and for a French chicken (4.4% fat) 0.45 µg vitamin D<sub>3</sub>/100 g and 0.29 µg 25(OH)D<sub>3</sub>/100 g [62,73]. Thus, chicken seems to show variations in the distribution of vitamin D<sub>3</sub>/25(OH)D<sub>3</sub> due to different vitamin D sources in feed, as both vitamin D<sub>3</sub> as well as 25(OH)D<sub>3</sub> are approved in feed for chickens [111]. UVB-exposure to hen is most effective to the nonfeathered areas such as legs, comb, and wattles and may show an increase per 100 g of approx. 0.3 µg vitamin D<sub>3</sub> and 0.15 µg 25(OH)D<sub>3</sub> [60].

### 5.2.3 Beef

The first data on vitamin D in beef (average 6.1% fat) originated from Finland, which identified 0.06 µg vitamin D<sub>3</sub>/100 g and 0.06 µg 25(OH)D<sub>3</sub>/100 g [14], while Norwegian minced meat (13.2% fat) shows 0.09 µg vitamin D<sub>3</sub>/100 g and 0.003 µg 25(OH)D<sub>3</sub>/100 g [112]. The most comprehensive study of vitamin D in raw beef cuts included 48 individual samples of six difference cuts bought on the Danish market. The samples were of Danish origin and imported beef from 10

countries in Europe and South America. On average 9.5% fat, 0.093 µg vitamin D<sub>3</sub>/100 g, and 0.14 µg 25(OH)D<sub>3</sub>/100 g [73]. A dependence of vitamin D<sub>3</sub> and 25(OH)D<sub>3</sub> of fat content was not observed, while such dependence was identified in cuts from the same animal [72,73]. Investigation of the differences between the three breeds of steers, showed a significant difference in the content of vitamin D<sub>3</sub> in strip loin, while no differences were observed in the liver [113]. The content of vitamin D in beef may be manipulated to a higher content by increasing the level of vitamin D in the feed. The approved sources of vitamin D<sub>2</sub> are less effective than the sources of vitamin D<sub>3</sub> and 25(OH)D<sub>3</sub> to transfer vitamin D to animal flesh [114,115]. Furthermore, the effect of higher levels of vitamin D in feed or extra vitamin D prior to slaughter increased tenderness of the flesh [114,116].

### 5.2.4 Organs

The liver in fish is a storage site for vitamin D. In humans, as a representative of mammals, an estimate is that 65% of vitamin D in the body is represented by vitamin D, and 35% as 25(OH)D<sub>3</sub>, and that vitamin D is primarily stored in fat, while 25(OH)D is distributed throughout in fat, serum, muscle, and other tissues [117]. Few specific data are available for vitamin D vitamers in the liver, kidney, and heart in pigs, beef, and lamb. The highest level is reported in the liver, though the reported content shows huge differences in the range 0.05–1.2 µg vitamin D<sub>3</sub>/100 g and 0.08–0.53 µg 25(OH)D<sub>3</sub>/100 g [14,73,118]. See Fig. 55.6.

### 5.2.5 Mushrooms

UVB-exposure during or postharvest of mushrooms, such as white button (*Agaricus bisporus*) resulted in an enhanced content of vitamin D<sub>2</sub> [76,119,120]. The UVB-exposure to mushrooms produces vitamin D<sub>2</sub> from lumesterol and tachysterol, but the amount depends on temperature due to the equilibrium between previtamin D ↔ vitamin D [121,122]. Mushrooms with vitamin D content are marketed, and in the EU the process is approved for a content of vitamin D up to 20 µg vitamin D/100 g [123] and in mushroom powder as an ingredient up to 2.1 µg vitamin D<sub>2</sub>/100 g in the final product [124,125].

### 5.2.6 Bread and other alternative vitamin D products

UVB-treatment of yeast has been known since the 1930s and is approved in the EU as a novel food to be used in bread production in an amount of 5 µg vitamin D<sub>2</sub>/100 g [126,127]. Vitamin D content has been reported in avocado, but recent investigation by the Danish Food Database showed a content <0.1 µg/100 g (vitamin D<sub>3</sub> and vitamin D<sub>2</sub>) [128,129]. Research into the effect of

FIGURE 55.6 The content of vitamin D in a variety of raw, food [14,73,81,95,118,167].

UVB-exposure to vegetable oil (avocado, canola, and wheat germ) shows that especially wheat germ oil may achieve a content of 8 µg vitamin D<sub>3</sub>/100 g and of 150 µg vitamin D<sub>2</sub>/100g [130].

For insects in a research feeding study, super worms are reported to contain 1.3 µg vitamin D<sub>2</sub>/100 g [131], while UVB exposure of yellow worms showed an increase to 15 µg vitamin D<sub>3</sub>/100g [132]. Furthermore, recent research indicates the possibility of genetically producing vitamin D in tomato [133].

### 5.3 Fortified food

A recent survey of fortification policies in European countries revealed that only two countries (Sweden and Belgium) like Canada in the North American continent have mandatory fortification of margarine and spreadable fat (7–28 µg vitamin D<sub>3</sub>/100 g), and 1 µg vitamin D<sub>3</sub>/100 g in Sweden (milk and sour milk) and in Canada (milk) [134–137]. Other vehicles are used in the voluntary fortification of food products. For example, in Belgium, cereals and cakes, juice, and lemonade may be fortified. More information on vitamin D fortification in food is presented in Chapter 58.

Vitamin D used in fortified food usually derives from ergosterol in yeast (vitamin D<sub>2</sub>) or lanosterol from wool (vitamin D<sub>3</sub>) [31]. The challenge for the producer is the stability of the added vitamin D due to the possible degradation mentioned above. Different encapsulation strategies have been studied, including different milk protein emulsifiers, vitamin D binding to milk protein,

vitamin D encapsulated by soy protein isolates, and vitamin D incorporated in mixed micelles have been tested to improve the solubility and stability toward heat and light [138–141].

### 5.4 Processing of food—effects on degradation of vitamin D

This section will provide information on how storage, household cooking, and industrial processes can affect vitamin D in foods. The combination of food and processing procedures is numerous but reported results on the changes in vitamin D during such processing are scarce. Some food, such as fruit, is eaten raw while others, such as meat and eggs, are processed. The reason for this is to improve edibility, digestibility, and palatability, but it might also improve nutritional value and decrease the risk to cause illness (due to microorganism). Especially for the industry, it is essential to enhance shelf life. Food processing can also give rise to new compounds (toxic or nutritional relevant) and decrease the palatability as well as the nutritional value.

Vitamin D as pure crystals or in solution is sensitive to light, heat, pH, and oxidation. The changes in the content of vitamin D due to the processing of food may be caused by degradation, and these will be evaluated, and described in detail in sections below: light (UVB/visible); heat (pasteurization/Boiling/Baking/Microwave); pH; Oxidation (oxygen/singlet oxygen); moisture content; and others processes such as drying/canning/fermentation. In the following

sections, retention of vitamin D is provided either as true retention (TR) or apparent retention (AR) and calculated on data for DM in the original paper. Content is given in per 100 g of edible portion, and e.g., for egg yolk transfer from per g DM to per 100 g fresh weight based on 7 g DM per egg yolk, 33% of an egg is yolk [97,142].

#### 5.4.1 Effect of exposure to light—not UVB

Vitamin D-fortified milk exposed to light showed a decrease in the content of vitamin D [29], which was later attributed to the content of riboflavin and the ability of riboflavin to act as a photosensitizer (see above). Thus, light should be omitted during the processing of milk to protect degradation of vitamin D. However, another study also revealed a loss of vitamin D if stored in darkness at 4°C for 21 days, which resulted in a retention in the range of 77%–88% [143].

A soybean oil fortified with vitamin D<sub>3</sub>, was stored in the dark for 1 month at 30°C followed by sunlight exposure for 1 month at room temperature, which should imitate the storage condition from manufacturer to consumer. The retention was 32%–39%, and the results indicated that  $\alpha$ -tocopherol as an antioxidant had a protective role in the degradation of vitamin D [144].

#### 5.4.2 Effect of temperature

Storage of canned swordfish in different filling media (olive oil, corn oil, sunflower oil, and high oleic sunflower oil) for 12 months at room temperature in darkness showed a vitamin D decrease of approximately 14%, which was independent of the filling oil [145]. Storage of eggs at room temperature followed by 1 week at 6°C showed that the natural content of vitamin D<sub>3</sub> and 25(OH)D<sub>3</sub> in eggs, had an AR >93% (Mattila, 1999). The degradation of vitamin D<sub>2</sub> in biofortified mushroom powder showed a first-order kinetic degradation at 20 degrees to 40°C, and the degradation rate increased by higher water activity [146]. Mushrooms stored at –20°C for 9 months showed no decrease [147], and storage at –18 to –20°C of homogenized samples of e.g., salmon, meat, and eggs, in dark and oxygen free for at least 10 years show no change in the content of vitamin D (Jakobsen, personal communication).

Vitamin D<sub>3</sub> in soybean oil stored for 1 month in the dark at 30°C showed ~100% retention [144]. Vitamin D-fortified dairy products such as milk, yoghurt, and cheese stored at 4°C have shown no loss within the shelf life of the product, neither was observed any loss in the content of vitamin D in cheese during ripening for up to 9 months [148–150]. Others stored vitamin D fortified Cheddar cheese for 7 months and report retention of 60%–89% [151]. Vitamin D-fortified milk powder stored at 20°C and 40°C, also showed a significant loss with a retention of 76%–62% after 12 months [152].

Vitamin D<sub>3</sub> fortified flour stored at 25°C or 45°C combined with relative humidity of 33% degraded over 120 days. The loss increased with the rise in temperature from 42% to 65% [153].

#### 5.4.3 Storage oxygenation

Vitamin D<sub>3</sub>-fortified skim milk treated with air showed a loss of vitamin D<sub>3</sub> of approx. 10% after 12 days [29].

#### 5.4.4 Relative humidity

Vitamin D<sub>3</sub> in flour stored at 25°C combined with an increase in relative humidity from 33% to 93% showed increased degradation after 120 days from 42% to 50% [153].

#### 5.4.5 Processing treatments

Industrial processing of swordfish (*Xiphias gladius*) included frying in olive oil (120°C for 6 min), which resulted in an AR of 84%. The fried swordfish was put in jars with different filling media (olive oil, corn oil, sunflower oil, and high oleic sunflower oil) and thermally treated at 115°C for 6 min. The sterilization caused no loss of vitamin D [145]. Boiling of trout (172°C–200°C for 20 min) showed a TR of 92% (78%–104%) [147]. Trout processed by eight different household cooking incl. boiling (110°C–210°C for 30–10 min), panfrying, steam cooking, and baking in an oven with and without foil showed an average retention of 96% (85%–114%). Only the lowest retention (85%) found for pan frying was significantly different from 100%, [154]. Cooking of nine different fish species (freshwater and marine) following household cooking in Thailand such as boiling (100°C for 4–10; one for 240 min), frying (110–150°C for 5–10 min), and grilling (230–250°C for 30–45 min) showed an average TR of 83% (47%–100%) (1 TR of 22% was evaluated as an outlier. Seven out of the 27 treatments had a TR significantly different from 100% [89].

In three independent studies, an egg boiled for 8–10 min showed vitamin D<sub>3</sub> a TR between 87% and 96% [95,155,156]. Processing of scrambled eggs (pan-fried for 3 min) and oven-baked (160°C for 40 min) retained 82% and 39% of vitamin D<sub>3</sub>. TR of 25(OH)D<sub>3</sub> showed similar levels as for vitamin D<sub>3</sub>.

For beef, the AR after traditional boiling, roasting, and braising of beef cuts, was 65%–69% [157,158]. Pork roasted with rind (in the oven 250°C for 20 min, 150°C until meat core 80°C) showed overall an AR of 85%, which for lean meat and lard were 100%, and for rind (crackling) 63% [80]. In contrast, crackling made from free-range pigs and UVB-exposed pork skin followed by baking (100°C for 60 min and 180 degrees for 45 min) showed a loss of 99 ± 1% [109].

Industrial processing by spray-drying vitamin D<sub>3</sub>-fortified milk resulted in an insignificant loss of vitamin D<sub>3</sub> [159]. In contrast, pasteurization of human donor milk in a water bath at 62.5°C for 30 min, resulted in a TR of vitamin D (vitamin D<sub>3</sub>, vitamin D<sub>2</sub>, 25(OH)D<sub>3</sub>, 25(OH)D<sub>2</sub>) of 80%–90% (assuming no change in weight) [160]. The temperature is below the risk for thermal isomerization to pyro/isopyrocalciferol, which was not the case in a study of cheese heated in the oven (232°C for 5 min), which caused an AR at 77%–80% (assuming no change in weight) [150].

Pan frying (5 min) of mushrooms resulted in a TR at 90% [147], while a variety of five processing methods (pan frying at high/low heat for 5min/20 min; boiling, in oven 70°C/90 min or 200°C/10 min) resulted in a TR of 74% (62%–88%) [154].

A model system for fortified canola oil (560 µg vitamin D<sub>3</sub>/100 mL) showed a TR of 100%, 68%, and 33%, at the temperatures of 100°C, 150°C and 180°C, respectively [161]. Heating of commercially fortified vitamin D<sub>3</sub> margarine in the oven (166°C for 40 min) and in a pan (3 min), showed a TR of 45% and 82%, respectively [155]. While sunflower oil heated in the oven (110°C for 30 min, 210 min, or 10 min), in a pan, or in a microwave for 1 min, resulting in TR for vitamin D<sub>3</sub> at 85%, 76%, 70%, and 84%, respectively [154]. Heating of vitamin D<sub>3</sub>-fortified oils (corn, sunflower, and canola) showed no effect for the type of oil used [162].

During the raising of dough fortified with vitamin D<sub>2</sub> and D<sub>3</sub> at 30°C for 60–120 min at room temperature no loss of vitamin D was observed [153]. Rye and wheat bread baked with vitamin D<sub>3</sub> fortified flour or vitamin D<sub>2</sub> enriched yeast, showed a TR in rye bread of 69% and 73%, respectively, while in wheat bread the TR was 85% and 89%. The cooking time for rye bread was 186°C for 60 min, which showed 90°C in the core of the bread, while for wheat bread the oven temperature was 170°C for 30 min, and the core temperature in the bread was 95°C. In contrast vitamin D<sub>3</sub> wheat bread baked at 200–205°C for 25 min showed a TR of 40%, and bread fried i.e., on a pan (170–180°C) for 10–20 s showed a TR of 10%, while chappatis fried on a pan (200–220°C) for 80–90 s resulted in a TR of 29% [153]. A cake baked at 172°C for 60 min to a core temperature of 100°C showed a vitamin D<sub>3</sub> retention at 39% [155], while cakes baked at 175–180°C for 25 min, resulted in a TR of 84%, and cookies baked at 200–205°C for 12 min the TR was 65% [153].

#### 5.4.6 Cooking—antioxidant/pH

In the boiling water of trout and mushrooms lemon juice was added as an antioxidant, but also lowered the pH (3.5–4.0). The TRs were 87% and 62% with antioxidants and 102% and 80%, respectively, without.

The authors stated no significant difference, thus further studies are needed to evaluate the possible effect [154].

#### 5.4.7 Food processing summary

Table 55.2 sums-up the treatment of foods which can cause vitamin D to become unstable or stable. Based on primary data collected for studies of household cooking a table showing the retentions is constructed. Only studies using specific chemical methods and reporting a minimum of two repetition for a cooking procedure are included. See Table 55.3. Retention studies need to be performed with strict guidelines such as timing, amount of food, temperature, and number of replicates (minimum three replicates). Furthermore, quality control similar to that performed for other analytical methods should be included. As mentioned, the optimal procedure is the use of true retention, which due to possible uncertainty should not exceed 120%.

Frying on a pan seems to degrade vitamin D to a higher extent than boiling, which is caused by the thermal degradation of vitamin D, potentially in combination with oxidation.

The significant difference between TR in rye bread and wheat bread seems not to be caused by the temperature but might be due to the higher content of water in rye bread. DM in rye bread is 54% and in wheat bread 64% [15]. The possibility of creating a model system that will illustrate the breakdown of vitamin D in foods is hampered by the challenges to determine each of the factors causing the degradation of vitamin D e.g., light, temperature, relative humidity/water activity, oxygen, and pH.

In the future, it would be beneficial to understand the degradation of vitamin D during the different treatments, and how to prevent this. High heat is obviously a cause for low retention, but it seems that water activity, relative humidity, and oxidation could be reasons for the relatively low retention during baking in the oven when the core temperature does not reach more than 100°C. Food databases may prioritize the content of raw food, and then the user will need to correct for retentions lower than 100% as shown in Table 3. Alternatively, food databases may prioritize to analyze processed food using a procedure, which is defined as the most common for the area/country of concern (UK; AUS). In this case, it would be beneficial to make the TR visible for the cooking process used.

### 5.5 Distribution of vitamin D vitamers in food and calculation of total vitamin D activity

The contribution of 25(OH)D<sub>3</sub> to vitamin D activity in food depends on the type of food, and not surprisingly,

**TABLE 55.3** Overall retention factors for vitamin D<sub>3</sub> in different foods by usual household cooking.

Type of food	Processing	Temp., °C	Time, min	Number <sup>a</sup>	% TR or % AR		Comments	References
					Average	Range		
Fish	Oven, pan-fried, boiled, microwave	100–250	4–45	40	86	49–114	AR estimated [145,166]	[89,145,147,154,166]

Beef, short loin	6	103	47	Do.

depends on the type of animal feed and access to sun and artificial UVB-exposure. In a country without mandatory fortification, and limited use of voluntary fortification, the amount of 25(OH)D<sub>3</sub> is approximately 20% and 33% of the ingested vitamin D<sub>3</sub> in adults and children, respectively [73]. The share decreases to approx. 11% with extra feeding of vitamin D<sub>3</sub> and/or use of UVB-exposure, but increase to approx. 67% (adult) and 108% (children) if 25(OH)D<sub>3</sub> is used as vitamin D source for animal husbandry [73].

It could be an easy task to calculate the total vitamin D activity in food by summing up the individual content of vitamin D<sub>3</sub>, 25(OH)D<sub>3</sub>, vitamin D<sub>2</sub>, and 25(OH)D<sub>2</sub>. Though debated, there is a consensus that vitamin D<sub>3</sub> and vitamin D<sub>2</sub> have the same bioactivity. Due to the minor difference in molar mass (vitamin D<sub>3</sub> ~ 384,64 and vitamin D<sub>2</sub> ~ 396,65) the content of vitamin D<sub>2</sub> is usually not corrected to vitamin D<sub>3</sub> equivalent. In contrast, there is no consensus for the activity of 25(OH)D<sub>3</sub> (or 25(OH)D<sub>2</sub>) compared to vitamin D<sub>3</sub>. The factor of five was introduced in research literature and then in food databases in the 1990's, but reviews have discussed the lacking documentation [56,163–165]. Due to the relatively high amount of 25(OH)D<sub>3</sub> compared to vitamin D<sub>3</sub>, it is essential to finally agree if, and if relevant, to what extent 25(OH)D<sub>3</sub> differs from vitamin D<sub>3</sub> in vitamin D activity.

The huge impact of vitamin D in food due to different animal breeds and fish strain, ocean versus farm living,

feeding system used, including access to sun- or artificial UVB-exposure, makes it essential to use area/country-specific food data. Food databases are essential, but it should be mentioned, that the number of original, primary, analytical data on food are very limited. Content for vitamin D in individual samples collected for food database and analyzed at the same laboratory show that the standard deviation for the average value for fish, eggs, pork, and beef for vitamin D<sub>3</sub> is in the range of 23%–114% (mean 62%; n = 14) and for 25(OH)D<sub>3</sub> in the range 27%–100% (mean 43%; n = 14). See Table 55.4.

The analytical precision for laboratories, which in general is <10%, (see above) does contribute to variation within a food type but is a minor contributor. Often composite samples are chosen to reduce analytical cost, thus no information on variation is available. Thus, it is essential that sampling is representative of the market intended. The limited number of sample types that have been analyzed forces data compilers to make assumptions, on which other food to choose as the most similar product, especially regarding the content of vitamin D. The data in food databases are advisable to use for the estimation of the dietary intake for a population. For an intervention study, the priority should be to analyze the food items, as the content of vitamin D depends on not only food type but the origin and type of animal feeding and breeding.

## 6. Conclusion

The lack of standardized methods, certified reference materials, and proficiency tests for quantification of 25(OH)D<sub>3</sub> in foods contribute to a higher uncertainty than for vitamin D<sub>3</sub>. Use of accredited methods should be used in projects aiming to establish new vitamin D data for food databases.

Vitamin D has a unique chemical structure, which enables isomerization to inactive forms due to light, heat, acid, oxygenation especially singlet oxygen, as well as water do have a negative influence on the stability in food. The content of vitamin D in food is very diverse—in wildlife, it depends on the season, breeding, and feeding.

Deficiency of vitamin D around the world is a problem, remembering the words from 1925, mentioned in the introduction, vitamin D may be increased through utilizing artificial UVB-light in indoor facilities and contribute to increased vitamin D levels in humans by biofortification making it possible to produce foods with targeted content of vitamin D.

## 7. Summary points

- The active vitamers in food are vitamin D<sub>3</sub>, 25(OH)D<sub>3</sub>, vitamin D<sub>2</sub> and 25(OH)D<sub>2</sub>.
- Vitamin D in food is susceptible to heat (>150°C) and singlet oxygenation.
- UVB exposure in husbandry or food enhance the content of vitamin D.
- Vitamin D in feed can enhance the content of vitamin D in food.
- Vitamin D in food is country or area specific.
- The total vitamin D activity of food might be estimated by summing up the content of the individual vitamers.

# Determinants of vitamin D levels from sun exposure: a global perspective

William B. Grant<sup>1</sup>, Harjit P. Bhattoa<sup>2</sup> and Pawel Pludowski<sup>3</sup>

<sup>1</sup>Sunlight, Nutrition, and Health Research Center, San Francisco, CA, United States <sup>2</sup>University of Debrecen, Debrecen, Hungary <sup>3</sup>The Children's Memorial Health Institute, Warsaw, Poland

## OBJECTIVES

- Understand the importance of sun exposure in determining 25-hydroxyvitamin D (25(OH)D) concentrations.
- Understand the seasonal nature of serum 25(OH)D concentrations.
- Learn about atmospheric effects on vitamin D production.
- Learn about endogenous effects on vitamin D production.
- Learn about behavioral effects on vitamin D production.

## 1. Introduction

Globally, serum 25-hydroxyvitamin D (25(OH)D) concentrations average about 50–55 nmol/L—nearly independent of latitude [1–6]. Although that similarity may seem paradoxical, the primary reason is that skin pigmentation varies inversely with latitude in general and that summer daylight times increase with latitude. The variation in pigmentation serves to balance production of vitamin D with protection against damage from free radicals and folate destruction by UV radiation [7]. Many observational studies report that adverse health outcomes are more likely as 25(OH)D concentrations decrease [8–11]. The Endocrine Society defines vitamin D deficiency as a 25(OH)D concentration below

50 nmol/L; vitamin D insufficiency is a 25(OH)D concentration of between 50 and 75 nmol/L [12]. Thus, about half the world's population is vitamin D deficient.

An estimate of the natural 25(OH)D concentration can be obtained from indigenous populations living in east Africa. A study examined two traditionally living populations there, one the pastoral Maasai and the other Hadzabe hunter-gatherers. Subjects had skin type VI, wear a moderate degree of clothing, and spend most of the day outdoors—but they avoid direct exposure to sunlight when possible. They had mean 25(OH)D concentrations of 115 nmol/L [13]. A study of pregnant women from five east African ethnic groups who consumed different amounts of fish found that solar ultraviolet B (UVB) exposure determined 25(OH)D concentrations and that the mean concentration was 115 nmol/L [14]. Those values correspond to an estimated daily production of vitamin D of 2000 IU [15]. On the other hand, a study in South Australia found that UV exposure led to a mean maximum 25(OH)D concentration of 89 nmol/L and was associated with an estimated mean weekly solar erythematous UV exposure of 1230 mJ/cm<sup>2</sup> [16]. Solar UV radiation at wavelengths 290–330 nm can destroy some vitamin D metabolites [17]. That effect limits the maximum 25(OH)D concentration resulting from solar UV exposure so that one cannot overdose on vitamin D from solar UVB exposure, as seen in the results from east Africa.

## 2. Vitamin D production from solar UVB exposure

An excellent systematic review and metaanalysis reported the impact of several factors on cutaneous vitamin D synthesis from UVB exposure [18]. One factor

is the part of the body exposed. The hands and face, which account for 3% of total body surface area (BSA), are eight times more effective in synthesizing vitamin D than the whole-body surface area. Another factor is that the increase in serum 25(OH)D concentration depends on baseline concentration. When the baseline is 21 nmol/L, the increase in terms of  $\Delta 25(\text{OH})\text{D}/\text{SED}/\% \text{BSA}$  is 0.093 where SED is standard erythemal dose, dropping to 0.004 for baseline 25(OH)D = 72 nmol/L.

Another review reported the change in 25(OH)D concentration with respect to simulated solar radiation [19]. It found that the change was linear in a logarithmic fashion: 10 standard vitamin D doses (SDDs), equivalent to about 12 SED, increased 25(OH)D by about 20 nmol/L, 100 SDDs by about 32 nmol/L, 500 SDDs by 46 nmol/L, and 1000 SDDs by about 52 nmol/L. A study in India found that men with a mean age of  $48 \pm 6$  years with 27% deficient and 41% insufficient 25(OH)D required greater than 1 h/day casual midday sunlight exposure to maintain 25(OH)D above 50 nmol/L and greater than 2 h/day for above 75 nmol/L [20].

### 3. Factors affecting 25-hydroxyvitamin D concentrations

Factors that affect 25(OH)D concentrations related to sun exposure fall under three broad categories [1]:

atmospheric and environmental determinants [2]; endogenous characteristics such as genetics and obesity; and [3] behavioral determinants. A recent paper reviewed the determinants of trends in vitamin D status [6]. Factors associated with decline include reduced sun exposure, increasing BMI, reduced consumption of vitamin D-containing foods, and the effects of urbanization, air pollution, less outdoor occupation, and poor socioeconomic status. Factors associated with increase include sun exposure on holidays, food fortification, increases in vitamin D supplementation, and increased physical activity.

#### 3.1 Seasonal changes in 25-hydroxyvitamin D

Solar UVB exposure is the major source of vitamin D for most people [21]. Table 56.1 shows winter and summer mean 25(OH)D concentrations for a representative sample of countries. The criteria for inclusion included that the 25(OH)D data were obtained after 2000, that they were for adults with data for elderly preferred, that the assays used were considered relatively accurate, and that a sufficient number of participants were included. The data from the various countries have some differences such as the age ranges of the participants, the selection of participants, and the periods considered summer and winter. Nonetheless, the data are very useful.

**TABLE 56.1** Seasonal changes in 25-hydroxyvitamin D (25(OH)D) concentrations.

Country, latitude	Population	Period	25(OH)D concentration (nmol/L) in:		References
			Winter	Summer	
Australia 19 to 43 degrees S	~250 in each of 4 cities, 18–75 years	2009–10	51 $\pm$ 23	74 $\pm$ 24	[22]
Australia 35 degrees S	3523		M 67 F 63	M 84 F 71	[23]
China 23 degrees N	M & F, <18 to >80 years	2018–19	73 $\pm$ 25	88 $\pm$ 25	[24]
Denmark 56 degrees N	F, 70–75 years	2002–03	49	67	[25]
Estonia 59 degrees N	367 M, F, mean 49 $\pm$ 12 years	2006	44 $\pm$ 15	59 $\pm$ 18	[26]
Germany 48.4 degrees N	1418 M + F, >65 years	2009–10	39 $\pm$ 3	63 $\pm$ 4	[27]

United Arab Emirates 24 degrees N	M & F, university students	2009–10	31	21	[47]
United States 26–48 degrees N	Adults	2007–09	54	71	[48]

Fig. 56.1 also raises the question of what determines serum 25(OH)D concentrations in winter in the absence of solar UVB. Two recent articles made the case that the primary mechanism for maintaining 25(OH)D concentrations in the absence of solar UVB is the storage of 25(OH)D in muscle cells [49,50]. They proposed that parathyroid hormone controlled the recirculation process. The linear regressions in Fig. 56.1 can also be used to estimate the relative contributions of oral vitamin D intake and solar UVB in winter. Let us assume that all of the oral intake of vitamin D is from food. Animal sources are the only source of vitamin D, ignoring that from fungi, with meat and fish accounting for the largest share [51]. Data from the Food and Agriculture Organization can be used to estimate the amount of animal products in the national diets (<https://www.fao.org/faostat/en/#data>, accessed June 15, 2022). Fig. 56.1 is a plot of summer and winter serum 25(OH)D concentrations for European countries using the

data from Table 56.1. What is interesting is that summertime mean concentrations for adults are near 68 nmol/L for all latitudes, while wintertime concentrations have a U-shaped relationship with latitude. The summertime effect can probably be explained as due to a combination of decreasing amount of skin pigmentation [7] and increased length of daily sunlight in summer with increasing latitude. The wintertime effect at high latitudes can be explained by the higher consumption of animal products that serve as sources of vitamin D at higher latitudes [51–53] as well as higher intake of vitamin D supplements [30] and food fortification such as in Finland [54]. The slight increase in 25\*(OH)D at lower latitudes can be explained by a longer duration of producing vitamin D from solar UVB exposure (see Ref. [55]). The finding regarding winter concentrations suggests that more countries should consider vitamin D fortification of food to raise wintertime 25(OH)D concentrations [56–58].

**FIGURE 56.1** Latitudinal dependence of summertime and wintertime 25(OH)D concentrations for adults in European countries using data in Table 56.1. The equation for the winter regression fit is  $25(\text{OH})\text{D} (\text{nmol/L}) = (170 - 5.4 \times \text{Latitude} + 0.057 \times \text{Latitude}^2) (\text{nmol/L})$ ,  $r = 0.72$ .

### 3.2 Geographic location and ultraviolet B doses: seasonal variations

The most important factor affecting vitamin D production from solar UVB exposure is the solar zenith angle (SZA). The spectral region for solar UVB reaching the earth's surface is 290–315 nm. Given the short wavelength, UVB is strongly scattered by atmospheric molecules. According to Rayleigh's model, scattering varies as the inverse fourth power of wavelength. In addition, stratospheric ozone affects UVB transmission. Thus, the longer the atmospheric path, the less UVB reaches earth's surface. A graph shows that UVB radiation at 310 nm reaching earth's surface drops by an order of magnitude in going from an SZA of 25–75 degrees [55]. For San Francisco on June 8, the SZA reaches 25 degrees at 1300 h (1:00 p.m.), falling to 75 degrees at 0745 and 1750 (<http://keisan.casio.com/exec/system/1224682277>). The general rule is that one can produce a reasonable amount of vitamin D for SZA <45 degrees. The SZA reaches these values that day at 0930 and 1610.

Figure 3 in Engelsen [55] indicates that vitamin D can be produced rapidly from solar UVB the entire year for latitudes <20 degrees, rising to 65 degrees in summer. However, it is impossible to produce vitamin D at the end of the year for latitudes >46 degrees, rising to 65 degrees by early March. From these calculations, it is estimated that for Fitzpatrick skin type III, one-quarter of a minimal erythemal dose over one-quarter of the body

would produce 1000 IU [59]. In Florida, that would take 8–15 min near solar noon, depending on the season.

The calculations in Engelsen [55] were based on the International Commission on Illumination (CIE) action spectrum for previtamin D production [60]. A recent paper pointed out some of the problems with the CIE action spectrum such as the use of a bandwidth of several nanometers in its determination [61]. Another was developed by the Dutch National Institute for Public Health and the Environment (RIVM) in the Netherlands [62]. In addition, that paper points out that prolonged UVB exposure saturates vitamin D production and that wavelengths between 310 and 330 nm cause photodecay of vitamin D metabolites. Although an improved action spectrum would probably make a few days change vitamin D production rates, the general conclusions reached using the CIE action spectrum offer good guidance for now.

Additional factors to consider include altitude, surface type, and aboveground features. UVB intensity increases about 19% per 1000 m for an SZA of 20 degrees [63]. The effect of altitude is evident in maps of vitamin D-producing UVB doses in the United States [64]. Different surfaces reflect different amounts of solar UVB. For overhead sun, reflectance varies from 10% for water, 12% for land, 23% for an alpine pasture, to 87% for new dry snow [63]. However, reflectance varies as a function of SZA; anyone who has spent much time on the water in summer knows how easy it is to get sunburned because of the high reflectance at higher SZAs. Living in forested regions reduces UVB doses. As a result, populations inhabiting forested tropical regions for centuries to millennia have lighter pigmentation than those who live in tropical plain regions [7].

### 3.3 Meteorological factors

Clouds can reduce the amount of UVB radiation reaching earth's surface. The degree of attenuation depends on the optical thickness/density of the cloud, the amount of cloud cover, and the SZA [65]. UVB can penetrate thin clouds. Coastal regions also can have considerable fog, which also attenuates UVB radiation reaching the surface. A good example is San Francisco, where the marine air passes through the Golden Gate in summer to cool the Sacramento Valley, bringing both clouds and fog.

Air pollution reduces vitamin D production by attenuating solar UVB radiation reaching earth's surface [66] as well as by reducing time spent outdoors [67]. In addition, since air pollution particulate matter perturbs over 500 genes including multiple proinflammatory

cytokines which vitamin D can counter [68], and since smoking reduces 25(OH)D concentrations [69], it is very likely that air pollution also reduces 25(OH)D concentrations due to vitamin D combating the inflammation and oxidative stress caused by the pollution [68]. The effect of urban pollution has been documented in studies in Belgium [70], China [71], France [72], India [73], and Iran [41,42]. Although aerosols may contribute most of the attenuation, gases that absorb in the UVB spectral region such as ozone and sulfur dioxide also can contribute [70]. In highly industrial regions of China and India, pollution can attenuate UV radiation by up to 50% [71]. Air pollution may also help explain the higher rates of vitamin D deficiency in urban regions than in rural regions.

### 3.4 Urban versus rural residence

Living in urban regions is often associated with lower 25(OH)D concentrations. A study of the effect of urbanization on South African women explored the reasons for lower 25(OH)D concentrations for urban dwellers. Several factors were investigated. The most important ones identified were higher urban rates of obesity, lower urban rates of physical activity levels, and greater urban alcohol consumption [74]. Another study from South Africa reported lower 25(OH)D concentrations among adolescents with alcohol use disorder [75]. Another reason for lower 25(OH)D concentrations in urban regions is due to a greater preponderance of indoor occupations [76]. High-rise buildings also reduce the UVB radiation reaching the surface [77]. A study of women of child-bearing age in Vietnam found slightly higher 25(OH)D concentrations in the Hai Dong province (85 nmol/L) than in Hanoi City (78 nmol/L) [78]. A study in Malaysia found that rural women spent much more time in the sun than urban women ( $\sim 8$  vs.  $\sim 3$  hour/day, respectively, resulting in higher 25(OH)D concentrations,  $\sim 70$  versus  $\sim 32$  nmol/L, respectively), even though urban women exposed more skin surface area than rural women [79]. A study of elderly Koreans found higher 25(OH)D concentrations in rural than in urban residence (66 vs. 43 nmol/L, respectively) [80].

### 3.5 Travel to sunny locations in winter

People who live at high latitudes and travel to sunny locations during winter have higher 25(OH)D concentrations. A study of Swedish women found that a winter sun vacation was associated with a 14.5-nmol/L increase in 25(OH)D concentration—greater than the 11.0-nmol/L increase associated with a daily intake of 300 IU of vitamin D from reduced fat dairy products [81]. A study in Europe found that sun holidays increased 25(OH)D

concentrations from 49 to 71 nmol/L for Danes and from 56 to 73 nmol/L for Spaniards; ski holidays increased 25(OH)D concentrations for Danes from 51 to 59 nmol/L [82]. However, the study also found significant increases in T–T dimers (also known as thymine–thymine or pyrimidine dimers), a biomarker of DNA damage, measured in the urine.

## 4. Endogenous characteristics

### 4.1 Effect of age

Vitamin D is produced in the skin when UVB acts on 7-dehydrocholesterol, followed by a thermal reaction [83]. As people age, the amount of 7-dehydrocholesterol in the skin changes. On the basis of those concentrations in the dermis and epidermis [84], the ability to produce vitamin D in the skin decreases linearly with time from 10 years of age, falling to about 50% lower ability by 70 years of age [83]. A study in Hungary found that August 25(OH)D concentrations decreased with age, from 42 nmol/L for those aged 0–9 years to 21 nmol/L for those aged 80–89 years [85]. This finding is probably due to a combination of younger people spending more time in the sun and producing vitamin D from solar UVB more efficiently. However, a study found that the US children do not generally spend enough time in the sun to meet nominal vitamin D requirements [86].

### 4.2 Obesity

The higher the body mass index (BMI), the lower the 25(OH)D concentration is likely to be [87]. One plausible explanation for this finding is vitamin D sequestration in adipose tissue [88]. Another is volumetric dilution [89]. A third is decreased hepatic 25-hydroxylase activity due to decreased expression of CYP2R1 [90]. Given the worldwide increases in rates of obesity, global 25(OH)D concentrations related to obesity will continue to decline.

### 4.3 Genetics

In a study of exposure to UVB lamps in winter in Denmark, 22 healthy participants achieved 25(OH)D concentrations from 85 to 216 nmol/L [91]. Baseline 25(OH)D concentrations accounted for 55% of the variance, whereas age, polymorphisms in the vitamin D receptor gene, height, and constitutive skin pigmentation accounted for 15% of the variance. Genes involved in the vitamin D metabolic pathway also can affect 25(OH)D concentrations. Alleles of these genes are associated with different 25(OH)D concentrations. The candidate genes are *DHCR7*, *CYP2R1*, and *GC* as shown by Brouwer-Brolsma [62]. *DHCR7* encodes the enzyme

7-dehydrocholesterol reductase. This enzyme catalyzes the conversion of 7-dehydrocholesterol into cholesterol in the skin, thus preventing that 7-dehydrocholesterol from being metabolized into previtamin D. *CYP2R1* encodes the liver enzyme that converts vitamin D to 25(OH)D. *GC* encodes the vitamin D-binding protein, which transports vitamin D metabolites to different organs, tissues, and cells. In a study involving 2857 Dutch men and women older than 65 years, 35% of 25(OH)D concentrations were explained by a model including sun exposure, oral vitamin D intake, and genetic factors [62]. In the model adjusted for age, BMI, years of education, smoking, alcohol consumption, physical activity, and self-reported health, the factors significantly affecting 25(OH)D concentration were the *GC* gene ( $P = 0.005$ ), being outside in the past 2 weeks ( $P = 0.01$ ), and sunlamp use ( $P = 0.03$ ). *CYP2R1* was marginally insignificant ( $P = 0.07$ ).

Another paper found that people with certain alleles of *CYP2R1* and *GC* had the smallest increases in 25(OH)D concentrations after UVB exposures and the largest decreases in 25(OH)D concentrations after 6 months of consumption of vitamin D<sub>3</sub>-fortified bread and milk [92]. Thus, genetics can modestly affect 25(OH)D concentrations from UVB exposure and oral vitamin D intake. Genome-wide association studies (GWAS) have identified genes associated with 25(OH)D concentration. A GWAS involving up to 79,366 participants of European descent added two loci harboring genome-wide significant variants of 25(OH)D concentration, rs8018720 in *SEC23A*, and rs10745742 in *AMDHD1* to four already known (*GC*, *NADSYN1/DHCR7*, *CYP2R1*, *CYP24A1*) [93]. Another GWAS involving 417,580 Europeans identified 143 independent loci [94].

## 5. Behavioral determinants

### 5.1 Use of sunscreen

Sunscreens generally block erythral wavelengths (<325 nm) well. The thicker the layer of sunscreen applied, the less the UVB reaches the skin [95]. Thus, if not applied thickly enough, some UVB will reach the skin [96]. In addition, sunscreen wears off. People who habitually apply sunscreen when in the sun will have lower 25(OH)D concentrations than those who do not, assuming similar sun exposures [97]. Many women's cosmetics contain sunscreen (<http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/cfrsearch.cfm?fr=700.35>). The primary reason for putting sunscreen in cosmetics is probably to reduce the risk of elastosis (wrinkling) [98].

An alternative to the use of sunscreen to reduce risk of erythema and DNA damage is to raise serum

25(OH)D concentrations using vitamin D<sub>3</sub> supplements. An intervention study conducted in Cleveland, OH, United States, found that raising 25(OH)D concentration to above 100 nmol/L using 200,000 IU of vitamin D<sub>3</sub> resulted in very little erythema for a sunburning UV dose compared with those supplemented with 100,000 IU vitamin D and achieving 25(OH)D near 75 nmol/L [99]. The mechanism indicated was inhibition of inducible nitric oxide synthase and TNF- $\alpha$  by activated macrophages [100], thereby reducing risk of inflammation. The Cleveland group also suggested using high-dose vitamin D<sub>3</sub> to treat sunburn [101]. The work was endorsed in an editorial by Bikle [102].

### 5.2 Shade

Atmospheric molecules and aerosols strongly scatter UVB radiation. There are two types of scatter involved: Rayleigh scattering is involved for particles up to about a 10th of the wavelength of light, while Mie scattering occurs for larger particles. Atmospheric molecules have a diameter of 0.4 nm, which is much smaller than 300 nm. Rayleigh scattering varies as the inverse fourth power of wavelength, whereas aerosols scatter to a lower extent, depending on particle size. The effect of scattering explains why the clear sky is blue and clouds are white during midday and orange at sunrise and sunset. Thus, UV exposure is related to direct, diffuse, and reflected UV radiation. A model calculation for Payerne, Switzerland, estimated that direct UV erythral radiation contributed 15%–24% of annual exposure, whereas diffuse radiation explained about 80% of cumulative erythral dose [103]. A study reported that for SZA between 35 and 60 degrees, previtamin D production under trees and umbrellas was about half of that in full sun [104]. A later paper reported that in Australia, the best time to expose the body to UV radiation while using a shaded environment with a sky view of >40% was when the SZA was <45 degrees [105]. Using that approach would reduce total UV exposure by 37%–58%.

### 5.3 Messages to get UV exposure mornings and afternoons (the shadow rule)

The UV index (UVI) is a commonly used indicator of erythral (skin reddening) potential of solar radiation introduced in Canada in 1992 [64]. The UVI is an irradiance scale computed by multiplying the erythral irradiance in Watts/m<sup>2</sup> by 40. The erythral action spectrum for solar radiation has the highest value for below 300 nm and then decreases by a factor of 500 from 300 to 327 nm, and then more slowly out to 39 nm. The UVI multiplies the erythral action spectrum by the solar UV spectrum reaching the earth's

surface, which starts at 290 nm. The UVI peaks from 305 to 310 nm. Satellite instrument data are used to determine two important components of the UVI, total ozone, cloud, and aerosol effects. Surface altitude and latitude are also included. The UVI is given for solar noon.

In Australia, most people have skin pigmentation much lighter than appropriate for the UVB doses. Most people have Anglo-Celtic ethnic backgrounds. In the United Kingdom, the UVI often reaches 6 in summer, and people with Fitzpatrick skin type 2 could be in the sun for 30–60 min without burning (<http://www.weatheronline.co.uk/reports/wxfacts/The-UV-Index.htm>).

As a result, 25(OH)D concentrations for 45-year-old people living in England increase from 37 nmol/L in winter to 75 nmol/L at the end of summer just by going about their lives [28]. However, the Cancer Council of Victoria urges Australians to be “SunSmart” and cover up when the UVI is 3 or higher (<http://www.cancervic.org.au/preventing-cancer/be-sunsmart>). As a result, 25(OH)D concentrations of Australians are not as high as might be expected. A study based on serum 25(OH)D concentrations from women younger than 60 years in the period 1993–2001 found mean peak, monthly peak, and monthly trough values for three locations: South East Queensland (67.0, 75.3, and 54.6 nmol/L, respectively); Geelong region (75.5, 92.5, and 57.1 nmol/L, respectively); and Tasmania (51.1, 62.1, and 40.3 nmol/L, respectively) [106]. The authors’ concluding statement was “Current sun exposure practices and dietary intake do not seem to fully prevent vitamin D insufficiency and deficiency, and consideration should be given to modification of sun exposure advice or pursuing other means to achieve vitamin D adequacy.”

Dermatologists often recommend the shadow rule; i.e., use sun protection when one’s shadow is shorter than one’s height [107]. However, following the shadow rule greatly reduces the production of vitamin D and is associated with increases in risk of melanoma from the higher UVA to UVB ratio [108]. The abstract of the *European Code Against Cancer 4th Edition: Ultraviolet Radiation and Cancer* states: “Excessive exposure from natural sources can be avoided by seeking shade when the sun is strongest, by wearing appropriate clothing, and by appropriately applying sunscreens if direct sunlight is unavoidable. Exposure from artificial sources can be completely avoided by not using sunbeds. Beneficial effects of sun or UVR exposure, such as for vitamin D production, can be fully achieved while still avoiding too much sun exposure and the use of sunbeds” [109]. The Canadian guidelines for the prevention of nonmelanoma skin cancer (NMSC) recommend precautions when the UVI is 3–5, using protection (shade, cover up, wear a hat and sunglasses, use sunscreen) when

the UVI is 6–7, using extra precaution for UVI 8–10, and avoiding the sun more for UVI >11 [110].

Danish sun exposure guidelines recommend seeking shade, wearing a sun hat, wearing protective clothing, or using sunscreen. Adherence to the guidelines regarding seeking shade or wearing protective clothing always or often was associated with approximately 7–10 nmol/L lower 25(OH)D concentrations for adults in spring and autumn [111]. No clear associations were evident for children.

#### 5.4 Sun avoidance because of concern about skin cancer, melanoma

Public interest in the role of solar UV exposure and risk of melanoma and NMSC seems to have been sparked by reports that stratospheric ozone concentrations would be reduced by widespread use of chlorofluorocarbons [112]. In 1980, Australia began its “Slip! Slop! Slap!” campaign to get Australians to avoid the sun for UV indices above 3 [113]. A paper published in the *Journal of the American Academy of Dermatology* in 1982 reviewed the use of sunscreens for protection against the harmful effects of solar radiation [114]. People diagnosed with NMSC are more likely to try to minimize sun exposure through various means, including seeking shade, wearing clothing that exposes less of the body, and using sunscreen [115]. That effect also has been reported in an analysis of cancer rates among participants in the Women’s Health Initiative in the United States [116]. Women diagnosed with NMSC tended to have lower sun exposure in the decade of the study as well as increased risk of several cancers for which UVB reduces risk [117].

#### 5.5 Occupation (outdoors vs. indoors)

People who work outdoors generally have higher 25(OH)D concentrations than those who work indoors. A study in Israel found that outdoor workers had an average daily solar UVB exposure of  $4.4 \pm 1.6$  h, whereas indoor workers had  $0.9 \pm 0.5$  h, resulting in much higher 25(OH)D concentrations for the outdoor workers [118]. Rates of cancer incidence in Nordic countries offer another example of occupation’s effect on 25(OH)D concentrations. Workers in the occupations with most time outdoors, such as farmers, forestry workers, and gardeners, had the lowest rates of cancers for which UVB and vitamin D are associated with reduced risk [119]. Vitamin D production by solar UVB exposure is the only mechanism proposed to explain the link between UVB exposure and reduced cancer risk. A study of professional ballet dancers with mean age of 26 years in the United Kingdom found winter

and summer 25(OH)D concentrations of 37 and 60 nmol/L, respectively [120]. The dancers also had higher injury rates in winter. A study of males in Delhi in August–September found that outdoor, mixed outdoor–indoor, and indoor workers had sun indices of  $12.0 \pm 6.3$ ,  $4.3 \pm 2.2$ , and  $0.7 \pm 0.6$ , respectively, and mean serum 25(OH)D concentrations of  $73 \pm 22$ ,  $48 \pm 14$ , and  $27 \pm 11$  nmol/L, respectively [121]. The sun index was calculated as the product of sunshine exposure in hour/week and fraction of body surface exposed.

Working at night is also associated with reduced 25(OH)D concentrations. A study in Jordan found that female night shift workers had significantly lower 25(OH)D concentrations than day shift workers ( $50 \pm 38$  vs.  $73 \pm 35$  nmol/L) [122]. Male night shift workers had nonsignificantly lower 25(OH)D concentrations than day shift workers ( $55 \pm 25$  vs.  $65 \pm 33$  nmol/L). Also, a review of 10 studies found that shift workers and indoor workers were the occupational groups most likely to have vitamin D deficiency [123].

## 5.6 Outdoor recreational activities

Recreational activities, especially outdoors, can increase 25(OH)D concentrations. Younger people spend more free time outdoors. Analysis of NHANES data from 6370 people older than 18 years from 2003 to 2006 found that 10 min of objectively measured moderate to vigorous activities during the day were associated with an increase in serum 25(OH)D of 0.80 (95% confidence interval (CI) = 0.43–1.20) nmol/L [124]. A study in Italy found that serum 25(OH)D concentrations were about 25% higher for the elderly who regularly engaged in outdoor activities including brisk walking, cycling, gardening, and fishing [125].

## 5.7 Lack of knowledge of the benefits of vitamin D

A study in Hong Kong found that health literacy was directly associated with sunlight exposure, suggesting that health literacy training might be more effective than just providing information about vitamin D and sunlight exposure [126].

An important reason for low 25(OH)D concentrations appears to be lack of knowledge of the benefits of vitamin D, of the risks associated with vitamin D deficiency, and that the sun is an important source of vitamin D. A study of adults aged 20–40 years in Sharjah, United Arab Emirates, found that 39% knew about vitamin D deficiency and 43% of them knew that sunlight is the main source of vitamin D [127]. On the other hand, the elderly are becoming increasingly aware of the role of vitamin D in reducing risk of osteoporotic fractures

and are increasing their oral vitamin D intake. A study in France found that the ratio of 75-year-old women with 25(OH)D concentration <25 nmol/L fell from 69% before 2009 to 35% thereafter [128]. In the United States, analysis of data from NHANES found that age-adjusted mean 25(OH)D concentrations increased from 61 to 63 nmol/L between 1988–94 and 2005–06–67 nmol/L for the period 2007–10 [129]. The increase was attributed to increased vitamin D supplementation.

A study of 208 adult participants in the United Kingdom in 2018 found that 42% answered 4 or 5 of 10 vitamin D questions correctly, while 36% answered 6–10 correctly and 22% answered 1–4 correctly [130]. Forty four percent of the participants reported taking vitamin D supplements. Knowledge score was the strongest predictor of supplement use (odds ratio = 2.5 (95% CI, 1.2–5.3)). The most commonly reported reasons for use were insufficient sun exposure (57%), health benefits (51%), and insufficient amounts from food (46%). Another study conducted online in the United Kingdom during June 17–18, 2019 surveyed public awareness and behavior regarding vitamin D and sunlight exposure in the United Kingdom [131]. Among the findings was that 71% thought that the risks of sun exposure were well promoted versus 22% that thought the benefits of sun exposure were well promoted. Fifty two percent had increased awareness of the risks of sun exposure during the preceding 10 years, but only 24% noticed increased promotion of the benefits of sun exposure during the same period.

Unfortunately, an important reason for lack of knowledge about the health benefits of vitamin D is that the public health and medical systems consider randomized controlled trials (RCTs) to provide the most accurate information on health benefits of pharmaceutical drugs and, by extension, nutrients. Results of observational studies are generally not accepted for setting policies and guidelines. Unfortunately, RCTs of vitamin D for various health outcomes have generally not been designed, conducted, or analyzed properly. As outlined by Heaney [132], the guidelines for nutrients studies (such as for vitamin D supplementation to increase 25(OH)D concentration) include starting with an understanding of the nutrient concentration–health outcome relationship, measure the concentrations for prospective participants, try to enroll participants with low concentrations, supplement with sufficient nutrient to raise concentrations enough to have significant health benefits, and then measure the achieved concentrations. See, also [133]. Unfortunately, most vitamin D RCTs do not restrict their study populations to individuals with vitamin D deficiency [134]. Also, they generally use small vitamin D doses and do not base the analyses on achieved 25(OH)D concentrations. For example, an RCT regarding progression from prediabetes to diabetes

enrolled participants with a mean baseline 25(OH)D concentration of 28 ng/mL and gave participants in the treatment arm 4000 IU/d vitamin D<sub>3</sub> [135]. The hazard ratio for progression to diabetes according to intention to treat was insignificant, 0.88 (95% CI, 0.75–1.04,  $P = .12$ ). However, a subsequent secondary analysis, based on achieved 25(OH)D concentration in the treatment arm, found that the hazard ratio for conversion to diabetes was 0.75 (95% CI, 0.68–0.82) for every 10 ng/mL increase in 25(OH)D concentration above 20 ng/mL to >50 ng/mL [136]. Since it was a secondary analysis, it had little impact on health policy.

In addition, the medical systems such as in the United States consider vitamin D information and supplementation an obstacle to income and profits. As a result, the Disinformation Playbook has been used to discourage the dissemination of information regarding the benefits of vitamin D [137]. The five approaches include promoting bad vitamin D studies, harassing leading vitamin D researchers, manufacturing uncertainty, buying credibility for nonvitamin D approaches to health with academia and professional societies, and capturing government health policy agencies. Examples of these approaches are given in the posted analysis.

### 5.8 Lifestyle factors associated with reduced sun exposure

Both clothing and sun exposure behavior influence the effect of UV on vitamin D concentrations. Extremes of temperature, i.e., both hot and cold, have an impact. Although clothing traditions in equatorial societies are mainly highlighted, the same is true where the temperature is cold. Bedouins and Native Alaskans are traditionally clad from head to toe to prevent themselves from the harsh climate peculiar for their habitats and as such the temperature extremes that they are exposed to. Eventually, irrespective of the hours of sunshine theoretically available for endogenous vitamin D synthesis, the environmental temperature is a major determinant in sun exposure behavior. Studies from sunny countries such as Brazil have found that one of the major contributors of vitamin D insufficiency is seclusion to indoor activity [138].

Furthermore, clothing norms are dictated primarily by cultural following. Conservative societies, as is typical for the Arab world, demand a dress code that restricts the parts of the body exposed. Therefore, even with ample sunshine, type of clothing contributes to vitamin D deficiency. For example, vitamin D deficiency is prevalent among women and neonates in Saudi Arabia because of clothing traditions [139]. Lifestyle choices, such as sun avoidance, indoor work, and covered transport, also may be implicated in the prevalence of vitamin D insufficiency in countries with abundant

sunshine. For women in Morocco, lack of sun exposure and veiled clothing style were the most important factors that influenced hypovitaminosis D [140]. Skin pigmentation, religious belief, and lifestyle were among the major determinants contributing to the prevalence of vitamin D deficiency in South Asia and Southeast Asia [141]. Prevalence of vitamin D deficiency has likewise also been linked to less exposure to sunshine among healthy schoolchildren in central Ethiopia [142] and among Iranian adolescents [143]. A study listed the aforementioned as the major contributors in Cambodian women, despite their living close to the equator [144].

Pale skin has historically been prized as beautiful in China, and that concept is widespread in other Asian countries, such as India (<http://asiasociety.org/blog/asia/china-long-tradition-dodging-sun-photos>). Thus, aesthetically the preference of fair complexion has also retarded sun exposure in several Asian communities [145].

Cultural beliefs tend to prevail independently of country of domicile—particularly for the Asian diaspora. A study on South Asian women residing in Auckland, New Zealand, reported that deliberate sun avoidance and an indoor lifestyle were the major causes of hypovitaminosis D [146]. More sun protection behavior, shorter sun exposure on weekends, and less acculturation to the Australian lifestyle all were associated with vitamin D deficiency in East Asian women living in Sydney, Australia [147]. Primary healthcare patients of African and Asian origin in Sweden were at high risk of vitamin D deficiency [148]. A study of East Asian women living in Australia reported the following: “These women reported a number of cultural factors related to their attitudes and behaviors regarding sun exposure. They expressed preference for fair skin, a tradition of covering skin when outdoors, and no sunbathing culture. They believed that fair skin was more beautiful than tanned skin. They reported that beauty was the reason for active avoidance of sunlight exposure. Although they reported knowledge of the need for sun avoidance due to skin cancer risk, few reported knowledge about the benefits of sun exposure for adequate vitamin D levels” [147,149].

### 5.9 Migration/migrants

The global migrant/refugee crisis will probably exacerbate vitamin D deficiency. An increasing number of countries were recently confronted with hundreds of thousands of immigrants. In Germany, for example, the number of immigrants of European origin increased 1.3-fold between 2008 and 2015 [104,105]. At the same time, the number of immigrants from Africa increased 1.6-fold, whereas that from Middle East and Asia

increased 1.9-fold. Furthermore, the second generation from overseas-born migrants should be also considered a group at high risk for vitamin D deficiency because of darker skin pigmentation than the host population and reduced rate of full assimilation to the host society and its habits (lifestyle and diet). Dark-skinned immigrants in Europe have a significantly increased rate of rickets [150]. In the United States, African Americans have significantly lower 25(OH)D concentrations than European Americans and, therefore, increased risk for many types of disease [151].

Compared with the migrants' sunny homelands, most of the host countries (high income) are at higher latitudes with reduced efficacy of UVB, cloudy skies, pollution, low average temperatures, and short summer season (except Australia). As a consequence, clothing effectively prevents skin synthesis of vitamin D because of weather conditions or cultural and religious reasons. Unfortunately, the dietary preferences of migrants who relocated to higher latitudes may intensify their risk for vitamin D deficiency. Only a few natural food products are rich in vitamin D, so vitamin D-fortified foods and vitamin D supplements can serve as an alternative source. However, because of dietary preferences or economic status, immigrants may not consume commonly fortified staple foods or supplements [152]. Therefore, displacement from tropical regions to high-latitude countries puts immigrants at even greater risk of vitamin D deficiency than in their country of origin.

As shown by Mughal and colleagues [153], prolonged breastfeeding without maternal vitamin D supplementation to benefit the infant is another problem within immigrant societies that increase the risk of vitamin D deficiency and its consequences. Thus, exclusively breastfed infants consuming 750–1000 mL of breast milk per day from vitamin D-deficient mothers fail to receive the 10 µg/day of vitamin D needed to at least prevent bone mineralization defects [153]. A clinical trial showed that nursing women supplemented with 6400 IU/day of vitamin D<sub>3</sub> delivered 400 IU/day vitamin D<sub>3</sub> to the nursing infants [154].

In a study from Italy, severe vitamin D deficiency [25(OH)D < 25 nmol/L] was noted in 76% of migrant newborns and 48% of migrant mothers [155]. Both migrant newborns and migrant mothers had very low 25(OH)D concentrations ( $18 \pm 14$  and  $30 \pm 17$  nmol/L, respectively). Among the studied mother–infant pairs, a linear decrease of 25(OH)D concentrations was observed with increasing skin pigmentation (phototype I,  $42 \pm 18$  nmol/L, vs. phototype VI,  $18 \pm 10$  nmol/L;  $P < .0001$ ) [155]. For data analyzed by country of origin, host country newborns from Italy had 25(OH)D

concentrations higher than all migrant groups ( $P < .0001$ ) such as North African, African, Asian, Central–South American, and East European. The same results were found in host country mothers, and North African mothers and their offspring had the lowest 25(OH)D concentrations of  $22 \pm 11$  and  $13 \pm 10$  nmol/L, respectively [155]. In the Netherlands, 25(OH)D concentrations <50 nmol/L were identified in 82% of Surinamese, 92% of Turkish, and 93% of Moroccan pregnant women compared with 28% of native Dutch women [156].

In Belgium, 90% of Moroccans and 77% of Congolese had serum 25(OH)D concentrations <50 nmol/L [157]. In Norway, 92% of Pakistanis had 25(OH)D concentrations below 50 nmol/L [158], and 81% of newly arrived immigrants from the Middle East, 75% from South Asia, and 73% from Africa had 25(OH)D concentrations lower than 50 nmol/L [159]. Furthermore, from aforementioned regions, approximately one-third had 25(OH)D < 25 nmol/L [160]. Vitamin D deficiency appeared common among Pakistani immigrant children in Denmark [161]. Somali immigrant women had a high prevalence of vitamin D deficiency, defined as 25(OH)D < 50 nmol/L, with rates of 90% in Norway [162] and Finland [163].

A recent metaanalysis of dark-skinned migrant populations showed that immigrants from the extended Middle East and sub-Saharan Africa had a high prevalence of vitamin D deficiency (65% and 56%, respectively) [164]. Refugees are considered particularly at risk for vitamin D deficiency because of staying indoors to avoid potential harm from conflict in native countries and dangers associated with refugee camps [165]. Longer time spent in the host country is an additional risk factor for vitamin D deficiency, as suggested in the literature. In one study, the length of time living in Melbourne, Australia, was associated with increased risk of vitamin D deficiency (defined as 25(OH)D < 25 nmol/L) in African migrants, with a prevalence of 77% for those living >2 years in Melbourne compared with a prevalence of 38% for those living less than 2 years in that city [166]. The aforementioned phenomenon might be linked to asylum seekers dressing more conservatively since immigrating to Australia as well as reporting apartment-style accommodation and reduced time spent outdoors, further reducing sun exposure from that before they immigrated [166].

In migrant and refugee subpopulations, major risk factors for vitamin D deficiency include darker skin, Muslim religion, full body–covering clothing, longer stay in host country, decreased daylight exposure, living in an urban environment, and coming from a socioeconomically disadvantaged background. Prevention

programs with vitamin D supplementation should be considered in host countries, and migrants/refugees at high risk should be educated, screened, and monitored for vitamin D deficiency.

## 6. Predicting vitamin D deficiency

Diffey developed a model to estimate 25(OH)D concentrations from UV exposure in summer in the United Kingdom. He found that then-current advice to spend 10–20 min in the sun did little to boost overall 25(OH)D concentrations [167]. He extended that model later to include oral intake, finding that a combination of increased oral vitamin D intake in winter and increased summer sun exposure could improve vitamin D status for the adult British population [168]. His models were used to develop an integrated predictive model of population 25(OH)D concentration for Ireland on the basis of UVB data and vitamin D from food sources (4.4 µg/day or 180 IU/day). That model predicted well the 18%–19% of the population with 25(OH)D concentration <30 nmol/L in winter [169]. Evidently, 25(OH)D has a very slow decay rate, as shown by the fact that elderly patients who received vitamin D<sub>3</sub> in the form of fortified bread achieved a 25(OH)D concentration of 127 nmol/L, which decayed to 65 nmol/L after 1 year without the bread and 48 nmol/L at the end of 3 years [170].

Some researchers tried to predict vitamin D deficiency on the basis of several demographic characteristics and lifestyle factors. A cross-sectional study of 644 60- to 84-year-old participants in Australia found that use of “time outdoors, physical activity, vitamin D intake and ambient UVR, and inversely correlated with age, BMI, and poor self-reported health status” explained 21% of the variance in 25(OH)D concentration [171].

Another study in Amsterdam involved 1509 elderly Dutch participants in the development sample and 1100 in the validation sample [172]. “The final model for the prediction of vitamin D concentrations <30 nmol/L consisted of 10 predictors: older age, smoking, alcohol consumption (<13 drinks/wk), season, no vitamin supplement use, no bicycling, no gardening, medication use, limitations in the use of own or public transportation, and the inability to remember the present year, etc. The final prediction model for serum 25(OH)D < 50 nmol/L consisted of the following 13 variables: older age, sex (female), BMI (>30), smoking, alcohol consumption (<13 drinks/wk), season, no vitamin supplement use, no bicycling, no sporting, no gardening,

medication use, poor appetite, and without a partner.” The resulting model was sensitive to the upper 25(OH)D concentration cutoff. Table 4 in that article showed that the lower the cutoff concentration, the lower the specificity and the higher the sensitivity. Analysis of data from the Nurses’ Health Study and Nurses’ Health Study II in the United States found that for women, >10 g/day alcohol consumption raised 25(OH)D concentration by about the same amount as 7.5 µg/d (300 IU/d) vitamin D<sub>3</sub> intake [173].

A recent study based on analysis of 201 healthy individuals between the ages of 20 and 40 years identified male sex ( $P < .001$ ), taking 50,000 IU vitamin D<sub>3</sub> supplement monthly ( $P < .001$ ), and lower waist circumference ( $P = .02$ ) were identified as effective factors in increasing serum 25(OH)D levels [174]. It is difficult to predict serum 25(OH)D concentration with respect to vitamin D supplementation due to several factors including solar UVB exposure, BMI, dietary sources of vitamin D, and genetics. A figure posted at [Grassrootshealth.net](https://www.grassrootshealth.net/document/serum-25ohd-vs-vitamin-d-supplement-intake/) based on values for their volunteer cohort shows that while 25(OH)D concentration rises in a nonlinear manner from 100 nmol/L with no vitamin D supplementation to 240 nmol/L for 20,000 IU/d, there is considerable variability for any supplementation amount (<https://www.grassrootshealth.net/document/serum-25ohd-vs-vitamin-d-supplement-intake/> access ed March 22, 2022).

The question is often raised whether it is worthwhile to measure 25(OH)D concentrations especially given cost considerations. One analysis suggested that it is when targeted at people likely to have vitamin D deficiency such as those with chronic diseases, having dark skin living at higher latitudes, and the elderly [175]. Regarding darker skin, see Ames et al. [151].

## 7. Nonvitamin D benefits from solar UV exposure

There is now good evidence that there are important health benefits from solar UV exposure in addition to vitamin D production. The primary mechanism is liberation of nitric oxide (NO) from intracutaneous nitrogen compounds, primarily nitrate, by UVA [176,177]. NO is known to reduce the risk of cardiovascular disease [178], and fight viral infections [179], among other things. In fact, it appears to explain the seasonality of many health outcomes with highest rates in winter and lowest in summer [180]. Solar UVA has been found to reduce risk of autoimmune diseases [181,182], blood pressure

[183], metabolic dysfunction [184], and COVID-19 [185]. The COVID-19 study was done in winter in Italy, the United Kingdom, and the United States, in locations where solar UVB doses were so low that vitamin D could not be produced. Thus, the additional health benefit of NO liberation should be considered an added incentive to spend time in the sun. For those who have limited access to sun exposure in any season, a UV lamp can be used to produce both vitamin D and NO [186].

## 8. Conclusion

Although solar UVB exposure is the most important source of vitamin D for most people, many factors affect 25(OH)D concentrations related to solar UVB doses. Some of these factors are physical, relating to solar, atmospheric, and surface properties and time of day. Others are related to lifestyle, such as time spent outdoors, clothing worn, and use of sunscreen. These factors are subject to societal factors, including attitudes toward sun exposure. Genetic factors play a role in skin pigmentation and are involved in the metabolism and transport of vitamin D. Since solar UVB exposure is subject to physical, cultural, and personal restraints, vitamin D food fortification and vitamin D supplementation would be required to have everyone avoid vitamin D deficiency [8,12,169].

## 9. Summary points

- Solar UVB exposure is the most source of vitamin D.
- Many factors affect 25(OH)D concentrations associated with solar UVB exposure including solar elevation angle, duration of sun exposure, amount of skin exposed, genetics, age, body mass, skin pigmentation including that from tanning.
- In Europe, the mean 25(OH)D concentration is near 68 nmol/L in summer for all countries; in winter there is a U-shaped relationship between 25(OH)D concentration and latitude, with lowest concentrations near 45–50 degrees N latitude. For all latitudes, 25(OH)D stored in muscles is recirculated in winter; concentrations are higher at the lower latitudes in winter due to longer duration of vitamin D production, and higher at the higher latitudes due to greater consumption of dietary sources of vitamin D including ocean fish and meat, as well as taking vitamin D supplements.
- An important reason for low 25(OH)D concentrations is that the medical and health systems have not embraced vitamin D supplementation for nonskeletal health effects due to the paucity of successful vitamin D supplementation RCTs. The failure of most vitamin

D RCTs is due to poor design, conduct, and analysis tied to not basing the trials on 25(OH)D concentration instead of vitamin D dose.

- There are additional health benefits from solar UV exposure due to nonvitamin D effects of UVB and increases in NO concentrations in the serum from UVA exposure.

# Vitamin D supplement use as a public health strategy to augment diet and sustain population adequacy

*Susan J. Whiting<sup>1</sup> and Mona S. Calvo<sup>2</sup>*

<sup>1</sup>College of Pharmacy and Nutrition, University of Saskatchewan, Saskatoon, SK, Canada

<sup>2</sup>Icahn School of Medicine at Mount Sinai, New York, NY, United States

## OBJECTIVES

- Describe inadequate vitamin D status as a worldwide problem present in countries where sun exposure and/or dietary sources are not widely used.
- Demonstrate that dietary supplements are used by otherwise healthy individuals to fill dietary gaps and vitamin D supplement users show better status than nonusers.
- Discuss, using Canada as a case study, the situation where vitamin D supplements are recommended by the Ministry of Health yet uptake in their use rose only modestly over a decade (2004–2015).
- Describe and discuss reasons for low uptake of vitamin D supplementation use.
- Present rationale for concluding that vitamin D supplement use cannot be an effective population health strategy unless better government guidance is provided and regulatory policies governing staple food fortification are established.

## 1. Introduction

Vitamin D deficiency is a recognized problem worldwide, and there is a pressing need to address ways in which adequate vitamin D status can be maintained in populations [1–3]. While sun exposure (providing ultraviolet B [UVB] rays) should be able to satisfy our need for vitamin D through dermal synthesis, there are environmental factors and personal characteristics that prevent or impede synthesis in the skin, and these are discussed in [Chapter 56](#). Many countries, especially those having prolonged “winter” during which time UVB levels are low or in countries where there is a “latitude–skin color mismatch” of people living there [4], must rely on dietary vitamin D to sustain adequate circulating concentrations of 25(OH)D. However, naturally rich food sources of vitamin D, which are primarily marine mammals and fish, are infrequently available or not consumed by choice. A major strategy to correct population micronutrient inadequacy, including vitamin D, involves the fortification of food to increase intake, a strategy that is covered in detail in [Chapter 58](#). As described in the following, national survey data show that total vitamin D intakes from natural food sources and even from foods that have been fortified do not meet current dietary recommendations for

vitamin D. Thus, another strategy is to encourage supplementation with vitamin D to fill the dietary gap. This chapter describes how current efforts to maintain adequate vitamin D intakes in most of the population can be enhanced by supplement use. A public health policy for safe, targeted, and effective use of vitamin D supplements needs to cover the majority of the population in an equitable way, which can present many challenges. The focus of this chapter questions: “Is it possible to maintain vitamin D adequacy in the population using supplementation?”

Table 57.1 shows the use of vitamin D supplements in three specific areas of health and medical care, which is an accepted and widely prescribed practice [6]. Many countries have recommendations of vitamin D supplement use for breast-fed infants (see Chapter 33), during pregnancy (see Chapter 32), and for disorders of liver (see Chapter 79), kidney (see Chapter 81), and gastrointestinal tract (see Chapter 97), which directly affect vitamin D metabolism as well as numerous diseases that are dependent upon vitamin D status. The use of vitamin D supplements in these diseases and medical

care examples is specific to individual patient’s need. In contrast, this chapter specifically addresses the use of vitamin D supplements by the general population over the age of 1 year for whom vitamin D supplementation can help to maintain status (for example, during winter months) or raise vitamin D status over a threshold for optimal health in an otherwise healthy individual. Unless specified, it is assumed supplements are in the form of the more widely available vitamin D<sub>3</sub> and are taken daily.

Recent evidence of the role of vitamin D supplementation in reducing risk of chronic disease and acute infections has sparked interest and research toward establishing higher thresholds of circulating 25(OH)D that are associated with the reduction in disease risk. The role of vitamin D supplement use in decreasing prevalence of inadequacy of vitamin D in the general population can be assessed using national intake and status data that allow monitoring of supplement use in

Recommendations for patients suffering from a disease	<ul style="list-style-type: none"> <li>Vitamin D supplementation guidelines that are disease-specific.</li> </ul>	Many disease-specific national or international guidelines related to

sustaining adequacy. Government guidelines providing citizens with basic education to encourage safe, targeted, and effective population use of vitamin D supplements are critical to the success of such a public health policy. The barriers we discuss center around inconsistent and ineffective messaging by governments and a lack of consensus from healthcare providers on the need for supplement use. Many of the examples we draw from are data from Canada, a country with a lengthy vitamin D winter 5–10 months long for most Canadians who live between latitude 42° and 84°N. It is a country that has mandatory vitamin D fortification of two staple foods, fluid cow milk, and margarine. As well, Canadians have access to regulated supplements that are safe, inexpensive, and available in pharmacies and health food stores. We show that despite these opportunities, the vitamin D status of many Canadians needs improvement.

## 2. Thresholds for 25(OH)D

To relate vitamin D intake to status, i.e., serum 25(OH)D measures, it is common to have a two-tier set of terms. “Deficiency” (sometimes called insufficiency) is defined as a level of serum 25(OH)D not able to provide protection against rickets/osteomalacia and osteoporosis, which represent the traditional outcomes of vitamin D deficiency. Most countries with published dietary vitamin D intake guidelines have set this level as < 50 nmol/L (20 ng/mL) [5], and there is near global consensus. To be above this cutoff is to achieve “sufficiency,” which is the term we use in this chapter for the lowest threshold of vitamin D status that is related to a health outcome. Each country-based report provides an intake called the recommended dietary allowance (RDA) or an equivalent dietary intake goal, which is the amount to maintain this level of sufficiency (50 nmol/L threshold) for most of the population in the absence of sun exposure (Table 57.2). The intake recommendation is intended as a guide for health policy decisions in that country for such initiatives as food fortification, food labels, and institutional feeding in schools, hospitals, and nursing homes. The RDA is the amount that an already healthy person needs to maintain health (e.g., in Canada and the United States, the RDA is to maintain bone health) and is, in most cases, calculated as the amount that will allow most of the population to achieve the adequacy threshold [7]. The EAR or estimated average requirement is the daily intake required to achieve circulating 25(OH)D concentrations of 40 nmol/L, which is the amount of vitamin D intake intended to meet the needs of half the population. For the purposes of this chapter, we refer to the RDA as

**TABLE 57.2** Institute of medicine’s (2011) nutrient reference values [7]. For the population aged 1 year and over, vitamin D set by Canada and the United States that have been adopted by other countries.

Age/Sex group	EAR <sup>a</sup> μg (IU)/day	RDA <sup>b</sup> μg (IU)/day
1–3 y M&F	10 (400)	15 (600)
4–8 y M&F	10 (400)	15 (600)
9–18 y M&F	10 (400)	15 (600)
19–70 y M&F	10 (400)	15 (600)
Over 70 y M&F	10 (400)	20 (800)

<sup>a</sup>EAR, estimated average requirement, is based on achieving 40 nmol/L serum 25(OH)D; it is intended to meet the requirement of half the population.

<sup>b</sup>RDA, recommended dietary allowance, is based on achieving 50 nmol/L serum 25(OH)D; it meets the needs of most of the population.

the intake guideline needed to sustain adequate vitamin D status, as this amount is the goal for individuals.

An “optimal” concentration of 25(OH)D is the second term often used when assessing vitamin D status. Here, the threshold represents the measure of circulating 25(OH)D based on emerging evidence of this threshold being associated with the reduction in risk of disease. Table 57.3 illustrates various health conditions established in different countries and the associated serum 25(OH)D threshold for optimal health. Among various countries, the lowest threshold is the concentration associated with the prevention of severe deficiency (rickets and osteomalacia) and is the value set by the United Kingdom’s Scientific Advisory Committee on Nutrition (SACN) [9]; the United Kingdom notably has a high prevalence of rickets [10]. Next, at 50 nmol/L, is the threshold for bone health that was initially derived by the IOM in 2011 [7]. Some optimal thresholds shown in Table 57.3 are derived from an analysis of research studies showing significant reduction of risk for specific preventable illnesses and death, and most are attributed to vitamin D actions that include autocrine, paracrine, and intracrine functions—extraskelatal functions (see Chapter 9). Of these optimal thresholds, most are arrived at by combining results from multiple research designs appropriate to establishing requirements for a nutrient’s health effects [11], while one threshold, that of a reduction in autoimmune diseases, is based on results from a recent large randomized controlled trial called VITAL [12].

For the purposes of this chapter, discussion of vitamin D supplement use relies on results from research that compares outcomes of supplement users compared with nonusers in terms of achieving adequacy of vitamin D status compared with the requirement intake level and/or the deficiency threshold 25(OH)D concentration of the country. Most countries use the adequate

**TABLE 57.3** Serum 25(OH)D concentration thresholds for various health outcomes.

Values taken from

vitamin D status threshold for bone health, which is 50 nmol/L [5]. Some researchers, however, may compare outcomes at the higher thresholds depicted in Table 57.3, based on recent advances in vitamin D research. For example, Ames et al. [4] consider use of 4000 IU (100 µg) to achieve a 25(OH)D concentration of at least 75 nmol/L for African Americans, and the VITAL trial used 2000 IU (50 µg) to achieve a 25(OH)D level of (on average) 100 nmol/L for reduction in risk of several chronic diseases [12,14].

### 3. Country-level guidelines for supplements use

Supplements, when used for prevention, fill the gap between intake and requirement that may exist in a country that cannot be filled by other means such as fortification or sun exposure guidelines. Nations provide dietary guidelines so that the population can choose healthy yet culturally appropriate foods to meet nutritional needs. However, for vitamin D, food choices in countries that have no fortification or limited foods that are fortified, the selection pool of foods to provide natural vitamin D is small.

Some countries have provided guidance through their Ministries of Health or equivalent government department on the use of vitamin D supplements by the general population (Table 57.4). Finding these recommendations limited us to searchable statements that may not have identified all countries with vitamin D supplement guidance; although possibly incomplete, the list provides examples of varying government advice. Two countries (the United Kingdom, Hong Kong-SAR) specifically target lack of sun exposure for the general population as the main barrier to sustaining vitamin adequacy. For the United Kingdom, it recognizes that winter is a time when vitamin D synthesis is not possible, while Hong Kong, situated close to the equator, recognizes that being indoors or wearing clothes that cover most of the skin can lead to vitamin D deficiency. Four countries make supplementation recommendations specific to age: Canada (age 2–50 years and >50 years), Ireland and Switzerland (>65 years), and Finland (<18 years and “older people”). All but Hong Kong recommends a specific amount for supplementation: Canada recommends 400 IU (10 µg) daily, which was set in 2007; the more recent Swiss recommendation (released 2022) is 800 IU (20 µg); the Finnish recommendation for supplement use alone is 20 µg; for Ireland, a daily amount of 15 µg (600 IU) is specified; and for the United Kingdom, the supplement amount is 10 µg (400 IU) for all ages.

For recommendations shown in Table 57.4, it is not known if governments have monitored adherence to this guidance or plan to implement monitoring of the impact of these supplement recommendations in the future. In Canada, the initial recommendation (shown in the footnote) was implemented in 2007 as a feature of a new version of Canada's Food Guide, which was replaced in 2019. In the 2007 Canadian Food Guide, the vitamin D supplement recommendation was highly visible and is believed to have influenced supplement use. Canadian national surveys show an increase in supplement use by adults over 50 years of age between 2004 and 2015 [15]. For Canadian adults over 50 years of age, the percent who use D-supplements rose from about 45% to 55% for women over 50 years and from 30% to 35% for men over 50 years. These gains are quite modest considering the proportion of older adults taking a supplement falls short of the Canadian recommendation that everyone in this age group (>50 years) needs a supplement. The new recommendation for Canada (Table 57.4) better reflects current RDAs as indicated for everyone, not just those over 50 years may not get sufficient dietary vitamin D from foods alone.

The recommended supplement amounts made by the various governments (Table 57.4) are within the range of the RDA or equivalent values set to prevent severe deficiency or to ensure bone health with a circulating

**TABLE 57.4** Examples of advice and/or recommendations for citizens of a country to take a vitamin D supplement issued by the ministry of health or equivalent government body. Excludes Recommendations during pregnancy or for breast-fed infants.

Country	Organization	Recommendation	Reference or source
Canada	Health Canada <sup>a</sup>	"Include vitamin D from foods or a supplement every day. If you are between 2 and 50 years old: eat foods that contain vitamin D every day or take a daily supplement containing 400 IU (10 µg) of vitamin D. If you are 51 years of age and older: Take a daily supplement containing 400 IU (10 µg) of vitamin D; you can continue to eat foods that contain vitamin D as part of healthy eating."	<a href="https://www.canada.ca/en/health-canada/services/nutrients/vitamin-d.html#a2">https://www.canada.ca/en/health-canada/services/nutrients/vitamin-d.html#a2</a>

Talk about it beforehand with your doctor."	<a href="https://www.dsm.com/human-nutrition/en/talking-nutrition/switzerland-takes-positive-steps-towards-supporting-vitamin-d-status-in-older-adults.html">https://www.dsm.com/human-nutrition/en/talking-nutrition/switzerland-takes-positive-steps-towards-supporting-vitamin-d-status-in-older-adults.html</a>

<sup>a</sup>These recommendations were released May 2022. Prior to this date, the recommendations were as follows: "If you are over 50 years old, Health Canada recommends that you take a daily vitamin D supplement of 400 IU (equivalent to 10 µg)" and "Speak to your healthcare provider about taking a vitamin D supplement if you think you are not getting enough of it."

25(OH)D threshold goal of 50 nmol/L [5]. However, these intake recommendations would not be enough to reach any of the optimal levels of 25(OH)D for reducing risk of many chronic conditions shown in Table 57.3. As it is not common to have serum 25(OH)D analyzed in the general population, then dietary intakes of vitamin D are needed for guidance to estimate the likelihood of maintaining adequate D status. These RDA and equivalent values given as recommended levels of intake for vitamin D supplements should be as up to date as possible and must be relevant to current conditions of the targeted population. A case in point illustrating the need for effective intake advice is shown by the vitamin D supplement level recommendations issued by the Minister of Health in the United Kingdom from September 2020 to February 2021 in response to the early phase of the COVID-19 pandemic. The United Kingdom through the action of the Minister of Health made 400 IU supplements available at no cost to vulnerable populations during the pandemic lockdowns [16]. Nonetheless, many scientists believed that this low level of vitamin D was insufficient to meet increased immune protection that could be afforded by vitamin D and requested a higher dosage be made available for free to these vulnerable groups [17], but no increases have occurred and the debate continues.

#### 4. Supplement use improves vitamin D status: Canada as a case study

Canada is a country with mandatory vitamin D fortification of two staple foods, cow's milk and margarine, as well as voluntary fortification of other foods. Yet Canada has a high prevalence of vitamin D status inadequacy from those relying on foods alone (i.e., supplement nonusers). In 2015, mean vitamin D intake in the population not using supplemental vitamin D was only 4.2 µg/d (168 IU), and there was an overall 96.5% prevalence of poor vitamin D status measured in a national survey representative of the population for those 1 year and over as reported by the Canadian Community Health Survey (Table 57.5) [15]. Prevalence of inadequate vitamin D status or intake is a calculation of the proportion of the population that does not meet the RDA for intake or threshold for adequate status, 15–20 µg/d (600–800 IU) and 50 nmol/L 25(OH)D, respectively. The 2015 Canadian Community Health Survey (CCHS) measured dietary intakes year-round; thus, it collected over the winter months during which time the population in Canada experiences “vitamin D winter” for at least 5 months. As shown in Table 57.5, there were no differences in prevalence of intake inadequacy by age or sex for the nonusers, which is unusual considering differences in the amount of total food

intake between adults and children. An explanation can be gleaned from data that were analyzed in a previous CCHS conducted in 2004 when vitamin D intakes were no different from the 2015 daily intakes. In examining food sources of vitamin D by age groups, it was found that the children consumed more milk as a source of vitamin D, while adults ate more meat (including fish) and alternatives (including eggs) than children [15]. Hence, the vitamin D food sources of Canadians differed by age, with children reliant on a vitamin D–fortified food source and adults consuming more natural and unfortified foods containing vitamin D. Both age groups, however, fell short of reaching recommended intakes.

When the Canadian supplement users (33% of the population) were examined for vitamin D intakes in the 2015 CCHS, mean vitamin D intake was 14.1 µg/d (564 IU) and prevalence of inadequate intake at 14.1%, was markedly lower than for nonusers (Table 57.5) [15]. In contrast to the intakes from food alone by nonusers, intakes from foods alone and intakes from foods plus supplements varied by age and gender. For foods alone, intakes by supplement users were highest in males aged 14–30 years suggesting that this group was more health conscious than those who did not use supplements. For intakes from food and supplements together, the lowest vitamin D intake was 16.7 µg/d (668 IU) in children aged 1–8 years and the highest was 41.2 µg/d (1648 IU) in women ≥71 years. These survey data provide evidence that supplement use combined with mandatory food fortification enables more Canadians across age to meet the recommended intake levels of vitamin D.

The 2015 Canadian national nutrition survey showed only a modest increase of 5% in prevalence of supplement use from the 2004 intake survey. In 2015, there were 33% of the population 1 year and over taking a vitamin D supplement compared with 28% in 2004 [15]. The variability in proportion of supplement users in the population by age and gender is shown in Fig. 57.1. Those in the two oldest age groups had the highest percentage of use compared with younger subjects of the same sex in both surveys, and the increase in use by these older age groups was the main reason for the overall 5% rise in prevalence of supplement use of Canadians over 1 year of age. The 2007 Canada Food Guide recommended vitamin D supplement use that specifically targeted those over 50 years of age, and this recommendation has remained on the Health Canada website until May 2022 (Table 57.4). The recommended dose remains at 10 µg/d (400 IU); this supplement amount filled the gap between intake from food (200 IU) in 2004 and the vitamin D recommendations of 2007, which were 400 IU for those over 50 years and 600 IU for those over 70 years [18]. Higher RDAs for all age groups over 1 year of age, of 15 µg/d (600 IU)

**TABLE 57.5** Comparison of prevalence of inadequacy between supplement users and nonusers using nationally representative usual intake data from the Canadian Community Health Survey 2015.

Age and sex groups	Supplement nonusers		Supplement users		
	Vitamin D from all foods	Prevalence of inadequacy <sup>a</sup>	Vitamin D from all foods	Vitamin D from all foods + supplement	Prevalence of inadequacy <sup>a</sup>
F&M 1–8 y	µg/day 4.1 ± 0.2	% 99.0 ± 0.4	µg/day 5.3 ± 0.3	µg/day 16.7 ± 1.1	% 38.0 ± 3.4

Proportion of the Canadian population (age 6–79 y) with low 25(OH)D [ $<50$  nmol/L] with or without use of vitamin D-containing supplements in winter (W) and summer (S), and by self-reported nonwhite (NWh) ethnicity. Source: Whiting *et al.*, 2011 [19]

and 20  $\mu\text{g}/\text{d}$  (800 IU), respectively, were introduced by the IOM/Health Canada in 2011 [7]. These 2011 RDAs make the current supplement recommendation inadequate for those over 70 years. Health Canada has announced measures to improve fortification of staple foods in which amounts will be doubled for margarine and cow milk, with further provisions to allow more voluntary fortification with vitamin D. These new measures are slated for 2023.

Government guidance on vitamin D supplementation needs to stay informed about changes in dietary intake recommendations as insufficient doses can place much of the population at risk of not meeting the RDA, leading to inability to maintain adequate vitamin D status over winter. Promotion of vitamin D supplements for older adults likely stemmed from organizations such as Osteoporosis Canada ([www.Osteoporosis.ca](http://www.Osteoporosis.ca)), which may account for their higher use in older adults in 2004 that persisted in 2015. The lowest use of vitamin D-containing supplements was seen in males and females aged 4–18 years who typically are not concerned about osteoporosis.

Foremost in deciding the need for government advice on vitamin D supplementation of the population, a country should question whether there is substantial need since adequate sun exposure can have a large enough impact to mitigate deficiency due to a winter decline and/or other factors that block UVB exposure. For countries such as Canada, the best time to determine this is using survey data gathered during winter when most of the population is experiencing a lack of UVB as “vitamin D winter.” To this end, there is evidence that the 25(OH)D concentration of Canadians in winter is affected by supplement use [19]. Fig. 57.2 shows that for users of vitamin D supplements, the proportion of Canadians with circulating 25(OH)D less than 50 nmol/L ( $<20$  ng/mL) are well below that of nonusers in both winter and summer.

Of those who did not use supplements in winter or summer, over 50% had 25(OH)D levels  $<50$  nmol/L, while for those using supplements, only 17% in summer and 25% in winter were below 50 nmol/L. It should be noted that one-quarter of supplement users used a dose that was less than 10  $\mu\text{g}/\text{d}$  (400 IU), which may explain why some supplement users did not maintain adequate status during the entire survey collection period [20]. At the time of this survey collection (2007–09), the old recommendations of 1997 [18] were in use.

For Canadians who self-reported as an ethnicity with typically darker skin (i.e., who would be considered as nonwhite), those using vitamin D-containing supplements had half the prevalence of low 25(OH)D in winter (Fig. 57.2) [19] than those Canadians who did not use a supplement. Thus, it is apparent that users of vitamin D-containing supplements have better vitamin D status across race/ethnicity groups, despite differences in sun-blocking skin pigmentation. More importantly, those having darker skin color living in a country with a significant “vitamin D winter” should be encouraged to use supplements because the level of vitamin D fortification in Canada during the 2007–09 survey was not adequate. The recent change in supplement recommendations from Health Canada described in Table 57.4 also includes a statement that “many factors affect the amount of vitamin D the body makes from sunlight”; skin synthesis cannot be relied upon, and therefore, “a daily dietary source of vitamin D is recommended.”

Using data from nationally representative NHANES surveys in the United States, it appears that race/ethnicity can influence the use of supplements, which in turn affects vitamin D prevalence of inadequacy [21]. Table 57.6 shows vitamin D intakes for two darker skinned race/ethnic populations in the United States compared with whites (referred to as non-Hispanic White): non-Hispanic Black and Hispanic. For the two

**TABLE 57.6** Intake of vitamin D (food including beverages, fortified foods, supplements) by race/ethnicity, NHANES 2007–10.

Data are from Malek et al., 2019 [21].

minority groups, intake of vitamin D from supplements only is about 66% of that of the non-Hispanic White population; nonetheless, all groups taking vitamin D supplements markedly lowered the percentage with inadequate intakes. Demographic factors that influence the use of vitamin D-containing supplements in different populations are described in the next section and may relate to education, income and other factors that lead to health inequities.

## 5. Characteristics of vitamin D supplement users

National nutrition surveys can capture the demographic and socioeconomic characteristics of supplement users to determine whether supplement use can be an indicator of potential for health inequities. Table 57.7 presents the characteristics of Canadian supplement users along with adjusted odds ratios (ORs) that provide the likelihood of those in the Canadian population having used or not having used a vitamin D supplement [20]. Those ORs greater than 1 indicate greater likelihood of D supplement use. Adjustment was made for season, age, income, chronic diseases, and milk consumption. Age was not a consistent factor between males and females except for adults over 40 years of age, indicating both male and female older adults (>60 years) were much more likely to use supplements than younger groups. Being female was not consistently associated with supplement use. While older women were twice as likely to take vitamin D supplements as older men, this difference was not significant.

**TABLE 57.7** Likelihood of taking a supplement containing vitamin D (N = 5604) using nationally representative data from the Canadian Health Measures Survey cycle 1 (2007–09).

Characteristic	Adjusted odds ratio (95% confidence Interval)	
	Females	Males
<b>Age (y)</b>		
6–11	1.15 (0.67, 1.97)	1.77 <sup>a</sup> (1.19, 2.64)
12–19	0.63 <sup>a</sup> (0.41, 0.96)	0.58 (0.33, 1.02)
20–39	1.0 (Reference)	1.0 (Reference)
40–59	1.56 <sup>a</sup> (1.10, 2.20)	1.46 (0.77, 2.79)
60–79	4.19 <sup>a</sup> (2.69, 6.54)	2.41 <sup>a</sup> (1.54, 3.77)
<b>Income</b>		
Higher	2.29 <sup>a</sup> (1.26, 4.16)	2.12 <sup>a</sup> (1.49, 3.00)
Middle	1.59 <sup>a</sup> (1.03, 2.46)	1.55 <sup>a</sup> (1.04, 2.31)
Lower	1.0 (Reference)	1.0 (Reference)
<b>Chronic disease</b>		
At least one	1.48 <sup>a</sup> (1.06, 2.06)	1.29 (0.76, 2.18)
None	1.0 (Reference)	1.0 (Reference)

<sup>a</sup>Significant (CI does not overlap with reference group). Adjusted for season, age, income, chronic diseases, and milk consumption (females only). ORs greater than 1 indicate greater likelihood of D supplement use compared with the reference group. Reference [20].

Income was an important factor for supplement use. Using the lowest income group as the reference, those in middle- and higher-income groups were significantly more likely to be a user of a vitamin D supplement. This finding supports the “inverse supplement hypothesis” [22], which states that people at risk for inadequacy (and who also might need a greater amount of a nutrient because of disease risk) are not the ones who take supplements. Poverty and food insecurity could create a situation of poor nutritional status. Finally, females but not males, who reported having one or more diagnosed chronic disease such as cancer, hypertension, heart disease, or osteoporosis, were 50% more likely to take a vitamin D supplement. This is not unexpected as vitamin D is commonly included in calcium supplements, and both nutrients were recommended for osteoporosis prevention by groups such as Osteoporosis Canada [23].

Asking detailed questions about attitudes and perceptions of vitamin supplement use can be difficult in national surveys as these are time-consuming. A small survey from the United Kingdom published results in which a questionnaire was used to gather such information [24]. Shown in Table 57.8, the reasons for not taking a vitamin D supplement are outlined, with response

**TABLE 57.8** Reasons for not taking a vitamin D supplement: Respondents in a small study (n = 209) of adults in the United Kingdom.

Answers	% answers In affirmative
<b>Researchers predetermined responses</b>	
"I think I get enough"	36
Unaware of benefit of taking them/lack of research on benefit	26
"I don't know which one I should take"	22
I don't think it's important	9
Too expensive	4
I don't know how to get them	3
<b>Other participant answers</b>	
Forgetful/lazy/busy	10
Unnatural/dislike taking tablets	3

Reference [24].

prevalence noted. The answer given by one-third of participants was "I think I get enough," while one-quarter of the participants were not aware of any benefit. Taken all together including the reply "I don't think it's important" covers more than two-thirds of the responses failing to acknowledge the importance of adequate vitamin D intake. Expense was not important; however, the participants were well educated, thus suggesting they may have a higher-than-average income. Being busy or forgetful was answered by 10%. These findings suggest that education and awareness might be important aspects to consider by governments making recommendations on vitamin D supplement use for the general healthy public.

The participants from the O'Connor study [24] (Table 57.8) were highly educated and had volunteered for this survey, whereas, obtaining information from low income, less motivated participants is much more difficult. We have conducted focus groups with low-income Canadians who were compensated for their time, to secure information about healthy eating and supplement use in general [25]. We determined that there are five general barriers to healthful eating and to the use of vitamin/mineral supplements: knowledge, income, accessibility, health, and preferences. There were two concerns expressed by participants relevant to why vitamin D supplements might not be used by low-income groups. First, participants said that the cost was a factor in that supplements must be purchased all at once and that a daily estimated cost of \$0.10, while low, meant that money that would have gone for food or living expenses was diverted to a bottle of supplements that can range in cost up to \$20 - \$40 depending on size. Second, participants were not encouraged to take supplements by any authoritative source such as a health-care professional or government agency, and no effort was made to explain how supplements might be used to fill critical dietary gaps [25].

## 6. Considerations when choosing to take a vitamin D supplement

As was shown in Table 57.2, some governments have made supplement recommendations for the population. However, to say "take a supplement" now puts the consumer in the position of choosing the right supplement. What is listed in Box 57.1 are the many considerations that appear online in articles or advertisements directed at the public. Some are straightforward, and evidence is clear while for others there may be a lack of consensus

### BOX 57.1

#### Decisions consumers need to make when choosing a vitamin D supplement regimen

- Vitamin D<sub>2</sub> or D<sub>3</sub>
- Source of D<sub>3</sub>  
*Fish liver oil, lanolin, algal, lichen, synthetic*
- Daily or bolus
- Coingestion with a lipid source
- Coingestion with other micronutrients  
*Calcium, vitamin K, magnesium*
- Product quality

on key issues. Not shown here are cost, physical form of the supplement (tablet, liquid, gummy, spray, soft gel, chewable), and dose.

### 6.1 Type of vitamin D: D<sub>3</sub> or D<sub>2</sub>

There is historical as well as recent evidence that vitamin D<sub>2</sub> has similar activity and general functions in bone as vitamin D<sub>3</sub>, i.e., the form we synthesize in our skin with adequate UVB exposure. Recent research findings now point to concerns that vitamin D<sub>2</sub> does not replicate vitamin D<sub>3</sub> in all activities; thus, many believe D<sub>2</sub> supplements are less effective in promoting optimal health. The frequency of dosing is also different for D<sub>2</sub> and D<sub>3</sub> as shown in acute studies comparing the efficacy of vitamins D<sub>2</sub> and D<sub>3</sub> in raising serum 25(OH)D concentration. Vitamin D<sub>2</sub> is less effective than D<sub>3</sub> when given as a single bolus [26]. Over longer time periods, some studies show higher efficacy of D<sub>3</sub>, while others show equal efficacy [27]. A recent longitudinal analysis comparing vitamins D<sub>2</sub> and D<sub>3</sub> found they do not have similar effects on the human immune system [27] for which vitamin D supplementation has gained more attention because of the COVID-19 pandemic. Furthermore, availability of vitamin D<sub>2</sub> as an over-the-counter (OTC) supplement is often limited. For consumers purchasing vitamin D supplements, in many countries such as Canada, there are few vitamin D<sub>2</sub>-containing choices, underscoring the public preference for D<sub>3</sub> supplements. One large Canadian supplement manufacturer offers 21 products listed on its website, and none contained vitamin D<sub>2</sub>. Nevertheless, with online cross-border shopping, it is possible to obtain vitamin D<sub>2</sub>. Historically, the reason for continued individual preference for D<sub>2</sub> supplements and food fortification was understood to be avoidance of animal-derived products by vegans, vegetarians, and several cultural and religious groups. This reasoning may no longer hold since now there are vegan options for vitamin D<sub>3</sub> supplements, but not fortification other than the traditional use of D<sub>2</sub> from vegetative sources. Despite the continued controversy over vitamin D<sub>2</sub> efficacy, the fact remains that vitamin D<sub>2</sub> supplements and vitamin D<sub>2</sub> use in fortification are better than no supplementation or food fortification.

### 6.2 Sources of vitamin D<sub>3</sub>

The earliest vitamin D supplement was fish liver oil, and even today, this is often the choice of many who want to obtain both vitamin A and D, or for whom this is a traditional product. This product is listed in Table 57.7, which provides a list of various vitamin D-containing supplements. Fish liver oils are extracted

from either cod or halibut. The problem with fish liver oils is to their required extensive cleaning of these products and the need to reintroduce fat-soluble vitamins at levels not found in nature. Thus, they often contain low amounts of vitamin D along with high amounts of vitamin A as retinyl palmitate. For example, in Canada, some products have only 200 IU/dose (5 µg) of vitamin D yet may contain close to the upper level (3000 µg) of retinol. Retinol has the potential to interfere with vitamin D metabolism [28] although not enough research has been done to verify this relationship.

Most vitamin D<sub>3</sub> supplements are derived from lanolin, which is sourced from sheepskin and wool. In the process of cleaning wool, lanolin is extracted to be saponified, washed, and centrifuged to provide pure crystalline 7-dehydrocholesterol that is subsequently illuminated with UVB to form cholecalciferol [29]. Information of these processes is found at various company websites. Until recently, there were no concerns about using lanolin as the source of vitamin D in supplements except for vegetarians and vegans who would look for a yeast-derived source, which was vitamin D<sub>2</sub>. However, with vitamin D<sub>2</sub> no longer being considered as an equivalent to vitamin D<sub>3</sub>, many manufacturers have sought out plant- or algal-based vitamin D<sub>3</sub> sources.

There are now several vegan sources of vitamin D<sub>3</sub>: algal and lichen. Microalgae such as *Nannochloropsis oceanica* are able to produce vitamin D<sub>3</sub> when irradiated with UVB [30]. Algal supplements of vitamin D, however, are not widely available. There is at least one major company producing vitamin D<sub>3</sub> supplements using lichen. Lichens constitute a symbiotic association between a fungus and algae and/or cyanobacteria. The lichens grow in sparse clumps in northern regions like the Canadian tundra, but lichens used for supplements are farmed outdoors where vitamin D<sub>3</sub> is produced naturally.

### 6.3 Coingestion with a lipid source

As vitamin D is a fat-soluble vitamin, it would seem appropriate to recommend taking supplemental vitamin D with a lipid source; but not all studies show this to be necessary. In a study of the effectiveness of fortification, similar doses of vitamin D<sub>2</sub> were compared after adding to whole (full fat) milk, skim milk, corn oil on toast and ingested by adult subjects. Despite differences in fat content, there were no differences in absorption (measured as appearance of the parent molecule in the subsequent 72 h) [31]. The coingestion of vitamin D and lipid may be relevant to food fortification but not to OTC vitamin D<sub>3</sub> supplements based on current manufacturing sources. All vitamin D supplements sold have fat included in the tablet or drop, such as flaxseed or other plant oils,

or refined lipids such as magnesium stearate. The question has arisen whether one should consume a supplement with foods as this is commonly recommended for many nutrient-based supplements. In a systematic review of factors affecting vitamin D absorption, it was concluded, but using only weak evidence, that vitamin D was better absorbed when it was consumed with fat-containing meals and that absorption would occur without fat or oily vehicles [32].

## 6.4 Coingestion with another micronutrient

For several decades, calcium supplements have been sold with vitamin D as an additional active ingredient, to provide these two nutrients for prevention or treatment of osteoporosis. Ingestion at the same time is not required as it is not the parent compound, cholecalciferol, which stimulates calcium absorption but the active metabolite, 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ). Manufacturing supplements with calcium and vitamin D together was for consumer convenience.

Recently, vitamin D supplements containing vitamin K have appeared in the marketplace. Similar to the situation with calcium, the addition of vitamin K is for convenience. There is limited but biologically plausible evidence that vitamin K may mitigate vascular calcification and thus reduce the chances of excess vitamin D causing hypercalcemia. This is accomplished by Matrix Gla Protein (MGP), which is a small Gla vitamin K-dependent protein that acts as an inhibitor of calcification [33]. Often the form recommended is vitamin K<sub>2</sub>, which is found in fermented food but also can be made in vivo from the plant form of vitamin K, which is K<sub>1</sub> [34]. As intakes of vitamin D in a physiological range do not have risk of hypercalcemia, this additional vitamin K for the purposes of mitigating hypercalcemia is not essential. Future vitamin K recommendations will likely emerge for prevention and treatment of osteoporosis; thus, inclusion of vitamin K in a D supplement will facilitate taking two bone healthy nutrients [34]. Until recently in Canada, having vitamin K included in OTC supplements was not allowed due to risk of vitamin K promoting clot formation in those taking certain anticoagulants such as warfarin, but this restriction has been rescinded, in part due to availability of anticoagulants that are not vitamin K inhibitors.

Magnesium's role in vitamin D metabolism is actively being researched. Magnesium is emerging as being necessary in the biosynthesis, transport, and activation of vitamin D to its metabolites. With magnesium deficiency, there is impairment of parathyroid hormone (PTH), which in turn prevents renal  $1\alpha$ -hydroxylase-mediated synthesis of  $1,25(\text{OH})_2\text{D}$  [35]. One can purchase a supplement containing vitamin D and

magnesium together; it is usually recommended that magnesium supplements also be taken. Low magnesium intakes can be rectified through eating a healthy diet, for example, Canada's new Food Guide that recommends that half one's plate be filled with fruits and vegetables, provides enough magnesium to meet current recommendations yet is low in vitamin D [36]. In this case, a consumer would be advised to get magnesium from food and take a vitamin D supplement to fill the dietary gap.

## 6.5 Taking vitamin D supplements daily versus bolus dosing

The question arises about how often a vitamin D supplement should be taken, i.e., daily, weekly, monthly, or quarterly. All the government recommendations in Table 57.2 specify "daily." Yet it is well known in the pharmaceutical world that taking drugs less often improves adherence, and it is not uncommon to find medications such as oral bisphosphonates available in daily, weekly, or monthly formulations, with monthly having the highest compliance and persistence [37]. Vitamin D supplementations differ in that there is consensus that daily is the best course [38]. This is not to say that bolus dosing as a loading dose should be questioned, as this addresses a different function. This chapter is concerned with supplementation that maintains vitamin D status over time, not the issue of repletion—the latter circumstance responding well to bolus dosing. Further, the body needs all the metabolites of vitamin D, including the parent molecule [39]. The longest-lived metabolite is  $25(\text{OH})\text{D}$ , which has a half-life of about 2–3 weeks in the circulation and around 2–3 months for the whole body; in contrast, vitamin D has a half-life of roughly 24 h and the active form  $1,25(\text{OH})_2\text{D}$  is less than 12 h in the circulation [40]. The parent compound cholecalciferol should be available on a daily basis to ensure stable circulating concentrations.

## 6.6 Product quality

Globally the supplement industry has not always earned a good reputation for its supplement practices including making false claims for curing disease [41]. Different countries handle this industry in different ways. In Canada, nutrient-based supplements must have a natural product number (NPN) on the bottle. In the management of natural health products (NHPs) in the Canadian market, there is a strategy to address the most common issues such as contamination, adulteration, and deceptive or misleading advertising practices by regulating NHPs along with other health products available without a prescription (i.e., "over the counter,"

**TABLE 57.9** Vitamin D containing supplements in Canada available over-the-counter (OTC) in pharmacies and health food stores.

Brand Name or type of product	Vitamin D <sub>3</sub> Dosage on label <sup>a</sup>
Vitamin D supplement	400, 600, 1000, 2500 <sup>b</sup> IU
Multivitamin	400–1000 IU
Specific supplements, e.g., probiotic, immune	400–1000
Calcium supplement with vitamin D	50–400 IU
Vitamin D supplement with one other nutrient such as vitamin K or vitamin A	400, 500, 800, 1000 IU
Fish liver oil	200, 400 IU

<sup>a</sup>Amounts shown do not include overage amount that can be 20%.

OTC) in a single federal division [42]. The “NPN” is similar to a “DIN,” which is the drug identification number. Many supplements sold worldwide may have the letters USP (U.S. Pharmacopeia), which indicates this particular supplement has been tested for safety and quality by this non-Federal group working in alliance with the US Food and Drug Administration to ensure product safety.

## 7. Safety of vitamin D supplements

Table 57.9 shows a list of the variety of vitamin D supplements that are available for purchase without prescription from pharmacies and from stores selling natural food products in 2022 in Canada. When

examined by dose, supplement users in Canada whose data are plotted in Fig. 57.2 had a choice of using one or more products as a source of vitamin D. These survey data were collected in 2007–09, and at that time, a relatively small percentage of supplement users (16%) took a total dose >25 µg (1000 IU). Only recently has a product with a dose greater than 25 µg (1000 IU) been allowed to be sold, and it carries a very lengthy warning label created by Health Canada that is described in the following section addressing safety concerns (see Box 57.2). Consumers may also shop online, and this gives access to higher dosage levels available from other countries such as the United States where doses as high as 5000 IU (125 µg) may be sold OTC without prescription.

The dietary reference intakes included for the first time in 1997 an upper level (UL) of safe intake for vitamin D, also referred to as an upper limit in other countries [7,18,43]. These are shown in Table 57.10 and indicate near agreement in setting ULs between Canada/United Kingdom and Europe/United Kingdom. The ULs are primarily concerned with risk of adverse effects when supplement intakes, sometimes alone as in the case of folic acid, or in combination with food-derived intakes as is the case for vitamin D, approach levels that show measurable harm. The UL value itself, however, is considered safe for consumption and marks the beginning of increasing risk for adverse effects. In almost every case for a micronutrient (the exception being the current 1997 UL for magnesium) [18], the UL is considered to be chronic intake over a long period of time, not acute intake of a very high dose leading to immediate toxicity.

High intakes following self-dosing with excessive amounts of vitamin D supplements have been

### BOX 57.2

#### Warning label attached to a bottle of vitamin D supplements with dosage of 2500 IU (67.2 µg) introduced in 2022 to be permitted to be sold in Canada in pharmacies and health food stores.

Warning: keep out of reach of children and pets. 15–20 mcg (600–800 IU) of vitamin D per day is adequate for most individuals. Consult a healthcare practitioner to determine if you would benefit from additional vitamin D before taking this product. Do not use this product if you have hypercalcemia and/or hypercalciuria. Consult a healthcare practitioner prior to use if you are pregnant or breastfeeding; have a kidney disorder; take other vitamin D supplements, multivitamin supplements containing vitamin D, or products containing vitamin D analogs; take any recommendation medications including antacids, anticonvulsants, digoxin, cholestyramine, colestipol, mineral oil, steroids, statins, or thiazide diuretics. Stop use and consult a healthcare practitioner if weakness, fatigue, drowsiness, headache, lack of appetite, dry mouth, metallic taste, nausea, vomiting, vertigo, ringing in the ears, lack of coordination, and muscle weakness occur, which are early symptoms of hypercalcemia, or if you have any other side effects.

**TABLE 57.10** Comparison of safety assessments for vitamin D for healthy populations: Canada and United States (IOM), Europe (EFSA) and United Kingdom (SACN).

Country/ organization	Age	Upper level µg (IU)/day	Criterion for risk
Canada and United States (institute of medicine, IOM) 2011	0–0.5y	25 (1000)	Maintenance of a serum 25(OH)D level below 150 nmol/L of 125 µg (5000 IU)/day, and dividing by 1.25 UF
	0.5–1y	37.5 (1500)	
	1–3y	62.5 (2500)	
	4–8y	75 (3000)	
	9+ y	100 (4000)	
Europe (EFSA) 2012 and the United Kingdom (SACN) 2016	0–1y	25 (1000)	Risk of hypercalcemia UL set using NOAEL of 250 µg/day (10,000 IU/d), and dividing by 2.5 UF
	1–10y	50 (2000)	
	≥11y	100 (4000)	

NOAEL, no-observable-adverse-effect level; UF, uncertainly factor.

described, although the dose required to induce vitamin D toxicity is uncertain [44]. The major identifiable risk for vitamin D excess is hypercalcemia, which promotes calcification and thus damage of soft tissues. Vitamin D intoxication does not arise from the consumption of conventional foods (including fortified foods) or by excess exposure to UVB [45]. Cases have arisen, although, from accidental overfortification of milk with vitamin D<sub>3</sub>, from uncontrolled use of vitamin D mega doses, and from inappropriate use of vitamin D metabolites. Clinical signs of vitamin D toxicity include hypertension, hypercalcemia, hypercalciuria, and extraosseous calcification [45]. These clinical symptoms may arise after serum 25(OH)D levels exceed 250 nmol/L for an extended period of time.

The ULs are set for chronic exposure by the healthy population, not for those who may have genetic or other factors, which may predispose them to sensitivity to a nutrient. For example, those infants with the genetic disorder idiopathic infantile hypercalcemia experience symptoms of vitamin D toxicity at intakes no more than 500 IU [46]; the cause of this is mutations in gene for *CYP24A1*, which encodes the 24-hydroxylase enzyme responsible for inactivating vitamin D. These children are unable to metabolize vitamin D metabolites to inactive compounds to be excreted. Other causes of infantile hypercalcemia are being investigated [47]. Detailed information of this disorder is provided in Chapter 71.

In Table 57.10, ULs for vitamin D set in 2011 by the IOM [7] apply to Canada and the United States and have been adopted by many countries around the world. As is usual with setting ULs, a no-observable-adverse-effect level (NOAEL) was chosen based on

published data, which was a 5-month study using various doses of vitamin D [48] during which no adverse effects such as hypercalcemia or hypercalciuria were reported. The IOM panel used vitamin D intake of 5000 IU/day, which achieved serum 25(OH)D levels that ranged between 100 and 150 nmol/L and applied an uncertainty factor (UF) to bring this intake to 4000 IU (100 µg) per day. ULs for children under 9 years were adjusted downward to account for potential greater risk of high intakes. The European Food Safety Authority (EFSA) and the United Kingdom (SACN report) are similar to the 2011 IOM values, with small differences in ULs for children as well as cutoffs for ages [9,43].

ULs are used by governments to regulate the doses allowed in supplements as well as the extent of fortification in terms of the number of products and amount of vitamin D per serving. Governments can also use ULs to provide information to the public. In the case of Canada, doses of vitamin D allowed to be sold were restricted to 1000 IU (25 µg) per unit until 2021 when a product with 2500 IU (62.5 µg) was permitted to be sold (Table 57.9). The product having this allowable dosage has a very extensive Health Canada warning label affixed to the bottle (Box 57.2). This warning label describes vitamin D toxicity symptoms in both English and French as a safety precaution alerting the consumer. The label and warning insert does not use the term “UL.” It is likely that the permitted dose of 2500 IU was chosen as it is the UL for children aged 1–3 years and is under the UL specific to those age 4 and older (Table 57.10).

Since setting the UL for vitamin D, several other long-term studies of large doses of vitamin D have been published. A study of 4000 IU (100 µg) given to adults at risk for diabetes for 2.5 years reported no adverse effects from using this regimen [49]. Contrary to these earlier findings of safe use of high doses, a second randomized controlled trial (RCT) of high daily doses of vitamin D<sub>3</sub> (10,000 IU [250 µg]) and 4000 IU (100 µg) compared with 400 IU (10 µg) given over 3 years has provided new data on potential risk of high intakes of vitamin D on bone mineral density (BMD) in adults over 50 years of age [50,51].

Table 57.11 presents the results from this trial of 400 IU, 4000 IU, and 10,000 IU over 3 years in adults over 50 years of age. Achieved levels of serum 25(OH)D, the primary outcome that was the measurement of volumetric BMD, and adverse effects reported for this RCT are shown in Table 57.11 [50,51]. The group receiving 400 IU (10 µg) is considered the control group as their total intake of vitamin D from food and supplement was 600 IU (15 µg), which is the current adult RDA in Canada. Of note, baseline 25(OH)D levels for all participants living far north in Calgary averaged close to 75 nmol/L, an unusually high baseline for Calgary residents. The group receiving the lowest dose equivalent to less than

the RDA (400 IU) had no change from this high value over the 3-year period. At 3 months and 3 years, those receiving the UL (4000 IU [250 µg] per day) had serum 25(OH)D levels below 150 nmol/L (on average). Shown in the authors' published box and whisper plots, one can discern that circulating 25(OH)D was below 150 nmol/L for 75% of the group throughout the trial [51]. Of concern, the highest dose did put participants well over 150 nmol/L, with a 3-month average level at 188 nmol/L. By the 3-year end of the trial, the average had fallen to 144 nmol/L. The observed decline at 3 years in the 10,000 IU group had a problem with varying degrees of degradation of vitamin D at 18 and 36 months. The box and whisper plots at the 18-month timepoint showed 25% of these participants had 25(OH)D concentrations well over 200 nmol/L. Table 57.11 shows the primary outcome of BMD was not improved with additional vitamin D (over 15 µg, the RDA based on bone health), and there is indication of greater loss of volumetric BMD by women given the

two higher doses. There was transient hypercalciuria and hypercalcemia in the two higher dose groups that were resolved with reduction of dietary calcium. There were no observable clinical adverse event differences among the three groups.

## 8. Guidance is needed for use of vitamin D supplements

The UL for vitamin D was set to provide the public with an intake that should not be exceeded unless the person is under the care of a health provider. Several of the vitamin D supplement recommendations shown in Table 57.2 indicate the need to consult a physician or other healthcare provider when considering a supplement, and it may be that the general public likely does not know that ULs exist or what adverse effects could occur with high intakes of a fat-soluble micronutrient. To illustrate this lack of knowledge, we reanalyzed a study from the United States where vitamin D supplement use by seniors living in an assisted care nursing home was described [53]. Table 57.12 shows the residents' use of vitamin D supplements (as either D<sub>2</sub> or D<sub>3</sub>) by dosage amount compared with achieved 25(OH)D. Taking 100 µg (4000 IU) or less kept 25(OH)D measures below that of 150 nmol/L, but when intakes were above this amount, which is the UL, some of the residents were above 150 nmol/L. How the residents took vitamin D was described: as vitamin D alone (which in the United States could be as doses as high as 5000 IU), in calcium supplements, in multivitamins, or as a combination of more than one of those three options. The most effective supplements for achieving a serum 25(OH)D of 75 nmol/L were the D-alone and the combination, and the authors calculated that 37.5 µg (1500 IU) was sufficient for this purpose. In examining the data, we noted that people without

**TABLE 57.12** Use of vitamin D supplements by residents (>65 years) of nursing homes in Texas, United States (N = 173) who made personal choices for supplement use.

Supplement Dose	N (%)	Achieved mean 25(OH)D nmol/L
0 (none used) (Diet = 5 µg/d)	70 (40%)	60
10–20 µg/d (400–799 IU)	27 (16%)	73
20–50 µg/d (800–1999 IU)	30 (17%)	88
50–100 µg/d (2000–3999 IU)	30 (17%)	104
>100 µg/d (>4000 IU)	16 (9%)	133

guidance could be at risk of taking too little or too much, and we recommended a dietitian or other healthcare professional be available to assist residents in their choice of supplementation [54]. As noted in Table 57.8, people express confusion about selecting supplements.

A comparison between providing vitamin D using enhanced food fortification and that of supplementation was recently made by the ODIN consortium of vitamin D researchers (see Chapter 56 for further details). They conducted a systematic review of safety issues arising from increasing vitamin D intakes through fortification and by supplementation [55]. In food-based or supplement trials involving over 3300 participants, where vitamin D doses ranged between 5 and 175 µg/d, there were no reported adverse effects. However, the prevalence of high serum 25(OH)D (>125 nmol/L) was <10% when vitamin D supplements were administered, and only <0.1% for fortified foods. As there are restrictions of the amount of vitamin D added to foods as opposed to amounts provided in supplements, no guidance is thought to be necessary for the former strategy other than choosing the food that is fortified.

While health professionals who are trained in nutrition would be the best source of information on supplement use, ways to provide guidance can be found online. A browser search of "vitamin D calculators" brings up several options for this purpose. Table 57.13 provides examples of three such calculators. Each one uses slightly different criteria, but all have been influenced by the van Groningen et al. [56] cholecalciferol loading dose guideline for vitamin D-deficient adults, indicating that the values provided are a combination

of repletion and maintenance amounts of vitamin D. The published formula is  $dose\ (IU)\ to\ achieve\ 75\ nmol/L = 40[75 - serum\ 25(OH)D] \times body\ weight\ (kg)$ . This formula was generated using patient data. It is important to note that body weight made a large difference in the amount of vitamin D recommended by these online calculators. Yet there is no consensus on the role body weight plays in vitamin D status. The current Institute of Medicine RDA for vitamin D is defined as the amount of vitamin D needed to maintain serum 25(OH)D at 50 nmol/L for almost everyone in the population [7]. Yet the value of 15 µg (600 IU) per day is the same for a 12-kg child of 1-year-old as a 70-kg adult man (highest reference weight). No other nutrient has the same RDA for children and adults, which for vitamin D does, up to age 70 years.

A further point on body weight is the effect of obesity on vitamin D status. The 2011 Endocrine Society's recommendations for vitamin D classify obesity as a factor that puts people in an at-risk group for vitamin D deficiency and hence increases their requirements. This has been borne out by research, but there is some uncertainty as to whether obesity causes vitamin D deficiency through sequestering cholecalciferol and 25(OH)D in adipocytes [40] or whether the behavior of those who are obese cause them to avoid skin baring, thus reducing UVB exposure. Some evidence for the latter is that this relationship is not always seen in both men and women [57] nor is it stable through all seasons [58].

Overall, there is a need for guidance for the public to navigate the many considerations that exist for vitamin D supplementation. The United States offers leadership

in this regard by having an Office of Dietary Supplements (ODS) within the National Institutes of Health. The ODS provides information to the public as well as to health professionals. The Fact Sheets that are directed to health professionals are a model of evidence-based information and are updated yearly. Links to the scientific literature as well as to resources make this a useful resource. The 2021 Fact Sheet for vitamin D contains over 170 references, and each has a link to its PubMed abstract [59]. The Fact Sheet for the consumer is in a Q&A style that addresses most commonly asked questions. Consumers have access to the more detailed health professional version.

## 9. Conclusion

We asked the question: “Is it possible to sustain vitamin D adequacy in the whole population with vitamin D supplementation?” We used Canada as a case study, as it is a country with at least five or more months of “vitamin D winter.” While Canada enforces mandatory vitamin D fortification of two staple foods, this is at a level that is only able to maintain an average intake of 5 µg/d (200 IU) per day. In recognition of this low level of vitamin D in the food supply, a recommendation for D-supplement use in adults over 50 years of age began in 2007 by the Ministry of Health. This recommendation has recently been updated to better coincide with RDAs that were set in 2011 [7]. Previously the supplement recommendation in Canada only addressed people over 50 years of age. Between 2004 and 2015, there was a modest increase in the prevalence of supplement use, from 28% to 33% [15]. For those supplement users, probability of inadequate intake was very low, and status of vitamin D in winter showed only one-quarter of the population below 50 nmol/L, while over half of those not using supplements had insufficient intakes and could not sustain adequate vitamin D status over winter. Supplementation is efficacious and at intakes below the UL is safe. There are, however, barriers to having supplement use, on its own, as a public health strategy. Those who take supplements have higher incomes and levels of education, whereas those lower income nonusers may not be able to afford foods with added or natural vitamin D that are in reality luxury foods, such as enriched eggs and wild-caught sockeye salmon, respectively. There are often a potentially confusing array of supplement choices and considerations that may leave people confused. One study showed people taking supplements took levels that were too low and too high, pointing to the need for guidance from health providers and sound educational resources from government.

With respect to a practical application for supplement use, countries with long vitamin D winters for various reasons experience high prevalence of inadequate intake and poor vitamin D status and have no effective public health policies in place to increase intake and sustain adequate vitamin D status over time. The combined policies of mandatory fortification and national guidelines and education for vitamin D supplementation currently shown to be somewhat effective in Canada may serve as a roadmap for developing appropriate strategies to augment intake and sustain optimal vitamin D status in most of the population over time. Both mandatory, enforced vitamin D fortification of commonly consumed food staples and government-supported education and advice concerning appropriately targeted and safe dosing regimens for D supplement use are critical components to achieving these goals.

## 10. Summary points

- Vitamin D supplement use reduces prevalence of inadequacy of vitamin D intake and decreases the proportion of people with insufficient status.
- Governments can make recommendations for vitamin D supplement use that will encourage the population in their use.
- There is health inequity between people with low income and high income with respect to supplement use and this needs to be addressed.
- Guidance from health providers and educational resources from government is needed so people know what to take and how much.
- Combined government policies of mandatory fortification of food staples and national guidelines and education for vitamin D supplementation will likely be the most effective population strategy for maintaining adequate vitamin D status and dietary intake.

# Vitamin D and food fortification

Kevin D. Cashman<sup>1,2</sup> and Mairead Kiely<sup>1</sup>

<sup>1</sup>Cork Centre for Vitamin D and Nutrition Research, School of Food and Nutritional Sciences, University College Cork, Cork, Ireland <sup>2</sup>Department of Medicine, University College Cork, Cork, Ireland

## OBJECTIVES

- To provide a brief overview of the prevalence of low vitamin D status in Europe, North America, and other regions around the globe.
- To consider the current deficits between vitamin D intakes and dietary recommendations to meet vitamin D requirements.
- To evaluate the multiple strands of evidence for a role for food fortification using vitamin D<sub>3</sub>, D<sub>2</sub>, and 25-hydroxyvitamin D, both in nutrient addition and biofortification modes, in preventing low vitamin D status in the population.
- To consider safety aspects of different strategies for increasing vitamin D in the food supply.
- To recommend a pathway to translate knowledge into policy development and implementation for prevention of vitamin D deficiency in the population.

## 1. Introduction

The role of vitamin D in the development and maintenance of bone health is well established [1], and there is a growing body of evidence for an association between low vitamin D status and increased risk of nonskeletal adverse health outcomes (including cardiovascular disease, hypertension, diabetes, certain cancers) (Ref. [2], see chapters on *Vitamin D and Type 2 diabetes, metabolic syndrome and hypertension* by A. Pittas, *Vitamin D and cardiovascular disease and hypertension* by S.

Pilz, and *Epidemiology of Vitamin D and cancer risk* by E. Giovannucci; in the current works) as well as immune defense and respiratory infection [3]. Notwithstanding the importance of ongoing discussions with respect to serum 25-hydroxyvitamin D [25(OH)D] concentrations that may increase the risk of ill health, there is widespread acknowledgment that low serum 25(OH)D is widespread in the community, affecting many millions of people, and that there is a pressing need to address the problem [4]. Taking a serum 25(OH)D concentration of 30 nmol/L as the cutoff below which the risk of clinical vitamin D deficiency increases (manifesting as nutritional rickets in children and osteomalacia in adults), the first priority from a public health perspective is to ensure that this risk is minimized [4].

### 1.1 Prevalence of low vitamin D status

Estimates of the prevalence of very low vitamin D status (based on standardized serum 25(OH)D < 30 nmol/L) in representative population samples in the United States (US) ( $n = 16,180$ ) [5], Canada [6] ( $n = 8351$ ) and Europe ( $n = 55,844$ ) [7] have been reported as 5.0%, 8.8%, and 13%, respectively. Worrisome as they are from a population perspective, these estimates do not highlight those at highest risk in the community, as they do not capture the differences in prevalence of low vitamin D status caused by factors such as age, sex, seasonality, geographical location, and ethnicity that place many groups at higher risk, which is often masked by higher 25(OH)D concentrations among the majority. For example, the prevalence of serum 25(OH)D < 30 nmol/L increases from 8.2% in summer to 17.7% in winter in Europe [7], and from 3.3% in summer to 9.3% in winter in the United States, based on the

2007–10 *National Health and Nutrition Examination Survey* (NHANES) [8], as the most recently reported cycle of the survey (2011–14) adjusted prevalence estimates for season from 2003 onward [5].

Across ethnic groups within NHANES 2011–14, the prevalence of serum 25(OH)D < 30 nmol/L in non-Hispanic white, Hispanic, non-Hispanic Asian, and non-Hispanic blacks in the US was 2.1%, 5.9%, 7.6%, and 17.5%, respectively [5]. The Canadian survey showed that the prevalence of serum 25(OH)D concentrations <30 nmol/L in nonwhite participants was over threefold higher than that of white participants (20.1% *v.* 5.9%, respectively) [6]. Adolescents and young adults are at higher risk than other population life stage groups: within NHANES 2011–14, which included children, the prevalence of serum 25(OH)D concentrations <30 nmol/L was 0.5% and 1.4%, respectively, in those aged 1–5 and 6–11 years and increased to ~5% in 12- to 19-year-olds [5]. In both the United States and Canadian surveys, the prevalence of serum 25(OH)D concentrations <30 nmol/L was highest among younger adults (typically ~8%–11% in those aged about 20–50 years) than older adults (~3%–4%) [5,6].

Largely attributed to clothing practices, it has been noted that women and girls, especially in low-income and middle eastern countries, have lower 25(OH)D than their male counterparts [9,10]. In a recent systematic review of 83 low- and middle-income countries [11], Afghanistan, Pakistan, India, Tunisia, Syria, the West Bank and Gaza, and Mongolia were classified as “hot spots” for very low vitamin D status among women, pregnant women or infants on the basis of having a prevalence of 25(OH)D (<25–30 nmol/L) above 20%. In Africa, Mogire et al. [12] reviewed 133 studies including 21,591 participants from 23 African countries. Women and newborn infants were at particular risk, especially in the north of Africa and urban areas of South Africa, with a prevalence of 25(OH)D < 30 nmol/L of 18.5%.

Despite widespread speculation around higher cut-offs for serum 25(OH)D for public health, there are increasingly harmonized, albeit not universal [13], proposals among a number of authoritative agencies for a serum 25(OH)D concentration of 50 nmol/L as a threshold likely to meet the requirements of almost all “normal healthy persons” ([14–17]; and see Table 58.1), equivalent to a personal, or clinical, target. The average yearly population prevalence of standardized serum 25(OH)D < 50 nmol/L in Europe, the United States, and Canada is 40.4%, 23.3%, and 36.8%, respectively [5–7]. The prevalence of 25(OH)D <30 and <50 nmol/L for other parts of the Globe, especially those which do not have substantial fortification of food, has been reviewed recently [18] and can also be seen in Chapter 54 in the current book.

## 1.2 Dietary recommendations to meet the status gap

Dietary recommendations for vitamin D, devised for population, as opposed to individual (or clinical) use, are calculated from dose–response studies of the response of serum 25(OH)D in winter to graded vitamin D supplementation doses. They vary largely based on the population goal of the agency responsible for developing them and the conceptual frameworks used by those agencies for setting dietary recommendations, which vary slightly. Put simply, the goal can be either for everyone in the population to achieve a minimum 25(OH)D target, such as in the United Kingdom, where each individual is recommended to take 10 µg/day vitamin D (population protective goal based on moving 97.5% > 25 nmol/L) [13], or for the average intake in the population to achieve 10 µg/day (also a population goal known as the estimated average requirement (EAR), based on getting 50% above a 25(OH)D threshold of 40 nmol/L) in the case of the United States [14]. Both the United States and the European Union [14,17] also recommended 15–20 µg/day on an individual basis to achieve personal targets of 50 nmol/L, and although these values are useful for individuals, they cannot be applied to population evaluations and are not applicable to this discussion. Detailed reviews of the dietary recommendations for vitamin D are available [19,20].

## 1.3 Sources of vitamin D and the role of food in meeting nutritional requirements

The major source of vitamin D in humans is sunshine; UVB radiation (290–315 nm) stimulates cutaneous synthesis of cholecalciferol, which is stored in adipose tissue or undergoes hydroxylation in the liver to 25(OH)D [14]. Environmental factors, such as latitude and prevailing weather conditions, determine whether sunshine of sufficient strength is available to stimulate the conversion of 7-dehydrocholesterol in the skin to precholecalciferol [21]. Personal attributes, such as skin pigmentation, age, attire, sunscreen, working environment, physical activity, and sun exposure behavior, can also prevent or impede vitamin D synthesis [21]. For further information on sunlight and vitamin D, readers are referred to Chapter 3 and Chapter 56 of the current book.

People resident at latitudes greater than around 40 degrees rely on body stores and vitamin D in the diet to maintain healthy vitamin D status all year round. Vitamin D occurs in food, both naturally and as a fortificant, as cholecalciferol (vitamin D<sub>3</sub>) and ergocalciferol (vitamin D<sub>2</sub>) and also in nutritional supplements. The well-described winter nadir in circulating 25(OH)D concentrations means that body stores, which are dependent on UVB exposure, are inadequate to maintain

healthy vitamin D status all year round. Thus, the importance of vitamin D nutrition is the corollary of UVB exposure deficit [22]. This is problematic from a public health perspective, as there is considerable evidence that the dietary supply is currently unable to offset the UVB exposure deficit, which increases with latitude and the duration of winter [23], and aggravates other factors contributing to low vitamin D status, such as clothing customs. There are very few rich natural sources of vitamin D; these are oily fish and fish liver oil (which are consumed sporadically), egg yolk, and fortified foods, and vitamin D<sub>2</sub> is found in UV-exposed mushrooms or UV-irradiated yeast (see Chapter 55). Illustrated by analysis of the United Kingdom's food composition database, it is clear to see how scarce vitamin D is in the food supply [24,25]. Only 1% of food codes contain vitamin D in the range of 5–10 and >10 µg/100 g, respectively, and 3% contain 1.5–5 µg/100 g. Fish and fish products make up 70%–78% of the foods containing >5 µg/100 g and 35% of those containing 1.5–5 µg/100 g. Eggs and egg products and meat and meat products make up 17% and 10% of foods with 1.5–5 µg/100 g, respectively [24]. Given the low

consumption of fish and inaccessibility of naturally rich sources of vitamin D for many communities, as well as the global drive toward a more plant-based diet, this low supply is likely to be reduced further. Therefore, for many reasons, it is unrealistic to expect the usual diet of many countries to supply vitamin D at 10–20 µg/day across the population.

#### 1.4 Are dietary supplements the solution?

Vitamin D supplementation is often recommended to close this gap. In some countries, vitamin D supplement use has been recommended as national policy, particularly for at-risk population groups [26,27], especially infants [28,29]. This is not surprising in light of the tangible lines of evidence that vitamin D supplementation can significantly improve vitamin D intake and status [30] (see Chapter 56). For example, there have been a number of systematic reviews and metaanalyses of vitamin D randomized controlled trials (RCTs), which highlight the effectiveness of vitamin D supplementation in improving vitamin D status across a variety of age,

race, ethnic, and gender groups [31–34]. Beyond the controlled setting of RCTs, at a population level, there is evidence from nationally representative surveys that show relatively increased vitamin D status and a lower prevalence of vitamin D deficiency among participants stratified by consumption of vitamin D–containing supplements. For example, data from NHANES 2011–14 ( $\geq 1$  year,  $n = 16,180$ ) showed that the prevalence of serum 25(OH)D  $< 30$  nmol/L was 6.9% in nonsupplement users compared with 1.1% in supplement users [5]. However, relying on supplements as a public health strategy to increase intakes across the population has intrinsic limitations. Supplements are only effective in those who consume them, and uptake is usually lower than  $\sim 40\%$  overall, and highest among infants and older adults rather than children, adolescents and young adults, who are at high risk of deficiency [35–37].

The other consideration is safety. It is important to remember that vitamin D is a nutrient, and many authors now acknowledge that it is best taken in moderate amounts on a frequent, regular basis. Intermittent, high-dose regimens only correct deficiency in the short term and may have unintended adverse effects [38]. There is also potential for overdosing, particularly when supplement consumers are not under medical supervision. For example, the NHANES assessment of trends in supplementation shows that daily supplemental vitamin D intake of 100  $\mu\text{g}$  (the current tolerable upper intake level [UL] for vitamin D in adults [14]), or more, prior to 2005–06 was less than 0.1%, but thereafter climbed to 3.2% in 2013–14 [39]. While we acknowledge the usefulness of supplements under medical supervision for the rapid correction of clinical deficiency (serum 25(OH)D  $< 30$  nmol/L), risk management strategies for public health must be designed to meet the needs of the unsupervised majority, on an ongoing basis.

## 1.5 Food-based strategies are required

Thus, there is a need for sustainable food–based strategies to bridge the gap between current and recommended intakes of vitamin D to minimize the prevalence of low serum 25(OH)D concentrations, without increasing the risk of habitual excessive intakes. The distribution of vitamin D intakes is heavily skewed to the left, with a small number of high-dose supplement users at risk of excessive intakes [40]. From a public health perspective, we need to work toward changing the shape of the vitamin D intake distribution, thereby increasing intakes in the lower 50%, without changing the proportion with intakes close to the UL of 100  $\mu\text{g}/\text{day}$  [40]. Careful application of fortification (nutrient addition in controlled amounts) and biofortification (i.e., enrichment of animal food sources, such as meats, eggs, fish, vegetables,

mushrooms, by fortifying animal feed, and/or UVB irradiation of food products) could safely increase vitamin D in the usual food supply, thereby increasing intakes of vitamin D across the distribution without risking excessive dosing. Many countries have opted for mandatory or voluntary food fortification, with variable success [30,41,42]. The rest of this chapter will briefly overview the current dietary supply of vitamin D and illustrate the gap that exists between this supply and the dietary targets, and then consider the role of vitamin D–fortified and vitamin D–biofortified foods in tackling low vitamin D intakes. This will include the clinical evidence for efficacy of fortified and biofortified foods, as well as provide a brief discussion of some of the technical issues around fortification and biofortification, including the forms of vitamin D that can be used, addition amounts, and food vehicles. Finally, the chapter will highlight the types of studies/analysis/modeling required prior to initiating public health measures.

## 2. Current intakes of vitamin D in young and adult populations in North America and Europe and how these compare against dietary targets

We have previously provided a summary of vitamin D intakes and sources in adults and children, focusing on data from North America and Europe, which showed that intakes of vitamin D are inadequate ([23], and see Tables 58.2 and 58.3), and newer data have been reported in the past few years confirming these observations. In 2018, the national nutrition surveys in the 53 countries of the WHO European region were summarized, and the nutrient intake data (excluding that from supplements) were provided [43,44]. Vitamin D intakes from data collected between 2004 and 2015 in 21 countries from Northern, Western, Southern, and Central and Eastern Europe were available for adults. Intakes were low on average, at 2.7 and 3.3  $\mu\text{g}/\text{day}$  among females and males, respectively. Similarly, intake data from 13 countries across Europe collected between 2003 and 2016 were available for children; average intakes were 2.7 and 2.2  $\mu\text{g}/\text{day}$  for those aged  $< 10$  and  $\geq 10$  years, respectively. Regional differences were evident, with a general trend for higher intakes in the North compared with Central and Eastern Europe. Notwithstanding the differences introduced by varying methods of data collection and the coverage and accuracy of the food composition data, among the surveys that captured the relevant data, the main source of variation was the contribution from nutritional supplements [23]. This can increase mean intake values, providing a misleading view of the prevalence of low intakes. For example, the National Adult Nutrition Survey in Ireland can stratify nutrient intake data according to vitamin D

**TABLE 58.2** Vitamin D intakes ( $\mu\text{g}/\text{d}$ ) in adults from selected national nutrition surveys and cohort studies.

Country	Survey	Year	Sex	Age group (y)	N	Mean (SD) ( $\mu\text{g}$ )	Median (IQR) ( $\mu\text{g}$ )	Sources	National fortification policy

Modified from [23].

intakes from the base diet, the contribution from the fortification component, and the intake from supplements [45]. In the 2009 survey, fortification increased median [IQR] vitamin D in the base diet from 2.1 [1.8]  $\mu\text{g}$  to 3.7 [2.9]  $\mu\text{g}/\text{day}$  among fortified food consumers, who represented the majority (60%). With a 16% prevalence of vitamin D supplement use, consumers had a median [IQR] daily intake of 8.7 [7.2]  $\mu\text{g}$ , which increased the population mean to 5.0  $\mu\text{g}$  (the median was 3.5 [3.7]). Although 32% of supplement users had intakes  $> 10 \mu\text{g}/\text{day}$ , this had almost no effect on majority, with 95%  $< 10 \mu\text{g}$ . Many surveys still do not collect supplement data, and even fewer can disaggregate the fortification component, making it difficult to

disentangle the real sources of vitamin D and the accuracy of inadequacy estimates.

In North America, NHANES 2011–14 ( $\geq 1$  year,  $n = 16,180$ ) reported a mean vitamin D intake (excluding supplements) of 4.9  $\mu\text{g}/\text{day}$  [5]. The prevalence of serum 25(OH)D  $< 30 \text{ nmol}/\text{L}$  was 7.1%, 4.7%, and 2.6% in those with vitamin D intake in the range 0–2.0, 2.1–5.1, and  $> 5.1 \mu\text{g}/\text{day}$ , respectively [5]. In NHANES 2009–12, vitamin D intakes from all sources (naturally occurring in foods plus enriched/fortified plus dietary supplements) were 14.2, 9.5, and 8.3  $\mu\text{g}/\text{day}$  for non-Hispanic White, non-Hispanic Black, and Hispanic population groups, respectively [46,47]. The Canadian Health Measures Survey 2015 ( $\geq 19$  years,

$n = 11,992$ ) [48] reported mean intakes of vitamin D of 5.1 and 4.2  $\mu\text{g}/\text{day}$  for males and females, respectively, from food sources only. This is noteworthy as in 2015, approximately 34% of Canadians took a vitamin D supplement, increasing from  $\sim 25\%$  to 30% in 31 to 50-year-olds to 37%–46% in adults aged 71 years and older [49]. Data from the 2004 cycle of the survey included children, with intakes in the range of 7–9  $\mu\text{g}/\text{day}$  in 1- to 18-year-olds [50]. Intakes among adults were higher (7.9 and 6.1  $\mu\text{g}/\text{day}$  for males and females, respectively, food sources only) in the 2004 survey [50] than the 2015 estimates [48].

As outlined before, the EAR for vitamin D is designed to meet the needs of 50% of the individuals in a life stage and gender group. This enables the evaluation of nutrient intakes on a population basis, as comparing the population intakes with the EAR provides an estimate of the prevalence of inadequate intakes. The absence of an EAR value means that evaluations of nutrient intakes in populations are subjective and difficult to interpret. While the prevalence of vitamin D intakes less than the US EAR of 10  $\mu\text{g}/\text{day}$  [14] was not provided in the collection of nutrition surveys of adults and children in countries within the WHO European region, it is clear from the mean intakes, which are typically below 5  $\mu\text{g}/\text{day}$ , that every country (with the exception of Finnish adults) has high majority with inadequate vitamin D intakes. Roman Vinas et al. [51] showed that of European national nutrition surveys reporting vitamin D intake data from 2000 onward, 77%–100% and 55%–100% of adults (19–64 years) and elderly ( $>64$  years), respectively, had vitamin D intakes below the EAR. In the United States, data from the NHANES 2009–12 showed that 72.5% of individuals (aged  $\geq 2$  years) had vitamin D intakes  $<$  EAR [46], whereas data from the Canadian Health Measures Survey 2015 ( $\geq 19$  years) suggest 94% and 98%, of males and females, respectively, had intakes  $<$  EAR [48]. Despite some small differences in the estimates, the overall picture illustrates beyond a doubt that the current dietary supply of vitamin D makes it unfeasible for almost all children and adults in Europe and many in North America to meet the 10  $\mu\text{g}/\text{day}$  target on a population basis. New dietary strategies to increase vitamin D intakes across the population distribution are required.

### 3. Dietary strategies for increasing vitamin D intake: bridging the gap by food fortification

The World Health Organization and Food and Agriculture Organization (WHO-FAO) have proposed a number of strategies for reducing micronutrient malnutrition [52], including (1) increasing the diversity of foods consumed, (2) food fortification, and (3)

supplementation. It should be noted that the WHO-FAO have indicated that all three strategies have pros and cons as well as implementation hurdles [52].

In a general sense, increasing dietary diversity is the preferred way of improving the nutrition of a population because it has the potential to improve the intake of many food constituents—not just micronutrients—simultaneously, and is potentially the most sustainable option [52]. Increasing dietary diversity means increasing both the quantity and the range of micronutrient-rich foods consumed [52]; however, in the context of vitamin D, this is particularly challenging because there are so few rich food sources. With recent calls for a radical transformation of the global food systems, with emphasis on increased consumption of plant-based foods and reductions in dairy and meat for many, increasing the intake of naturally occurring vitamin D-rich foods and increasing the diversity of vitamin D-containing foods are arguably unlikely strategies to achieve increases in vitamin D intakes [53].

Apart from the safety considerations around unsupervised dosing elaborated earlier, relying on supplements to increase intakes in the population has intrinsic and important limitations. The WHO-FAO suggest that while micronutrient supplementation often provides the fastest improvement in the micronutrient status of individuals or targeted population, food fortification tends to have a much wider and more sustained impact [52]. Further, as the benefits are potentially large, food fortification can be a very cost-effective public health intervention. Success, however, is predicated on widespread uptake and consumption by a large proportion of the target population [52].

#### 3.1 Traditional food fortification with vitamin D—what is the evidence?

Several lines of evidence, from national diet and health survey data to RCT, show that food fortification represents the best opportunity to increase the vitamin D supply to the population [23,54]. The practice of fortifying commonly consumed foods with micronutrients became widespread around the time of the World Wars to prevent micronutrient deficiencies and to address nutrient losses during food processing. By the 1930s, fortification of milk and cod liver oil supplementation of infants was widespread for the prevention of nutritional rickets. However, quality control was inadequate, and excessive addition of vitamin D to milk resulted in hypercalcemia among young children in the United Kingdom, which effectively ceased the practice of vitamin D fortification [23]. Countries vary considerably in their fortification regulations and practices. Calvo, Whiting, and colleagues have provided an

excellent overview of the North American vitamin D fortification initiatives and regulatory frameworks [55–57]. Canada currently has mandatory fortification of infant formula and medical nutrition products, milk, and margarine with vitamin D as well as egg products if their composition is altered by processing, as stipulated by the Canadian Food and Drug Regulations [58–62] (see Table 58.4). There is also voluntary fortification of butter substitutes, goat milks, and condensed milks. From a public health perspective, data on vitamin D status of Canadians who are not supplement users indicate that ingestion of at least 1 serving/day of fortified milk is associated with increments in serum 25(OH) D levels of at least 6 nmol/L per serving from November through April compared with nonmilk consumers [55,63].

While fluid milk in the United States is not required to have vitamin D added unless the label declares that it is fortified, in practice almost all milk is fortified with vitamin D on a voluntary basis [55–57,64,65]. The types of milks, dairy, and other foods that can be fortified in the United States are shown in Table 58.4, and it is of note, in recent years, the FDA in the United States have approved an increase in amount of vitamin D that may be added as an optional ingredient to milk (as vitamin D<sub>3</sub>) and milk alternatives and yogurts made from edible plants (as

vitamin D<sub>2</sub>) [64,65]. Calvo et al. [66] and Yetley [67] have highlighted that up until the first decade of the new millennium at least, most milk products such as yogurt, butter, ice cream, sour cream, cream, cottage cheese, and most varieties of hard and soft cheeses are not routinely fortified with vitamin D, which contradicts the widely held misperception that dairy products are rich sources of vitamin D [66].

In Europe, fortification practices vary between countries and may be applied voluntarily by manufacturers or implemented by national legislation. In the United Kingdom and Ireland, all margarine sold for domestic use was previously subject to mandatory fortification with vitamin D until recently [40]; currently, most margarines and fats spreads are still fortified with variable quantities on a voluntary basis. Other foods, such as breakfast cereals and dried or evaporated milks, may also be fortified on a voluntary basis as per the 2006 European Union regulation 1925/2006/EC on the addition of vitamins and minerals to foods.

### 3.2 A national case study—Finland

The Finnish experience over the past 10 years is exemplary and responsive with respect to not only implementation, but also evaluation of vitamin D fortification

**TABLE 58.4** Foods fortified with vitamin D in North American and select Nordic countries (excluding infant formula and medical nutrition products).

Country	Type of fortification	Foods fortified with vitamin D	Amount of vitamin D added
Canada	Mandatory	Margarine	530 IU/100 g
		Milk	33–45 IU/100 mL
		Milk products: milk Powder, sterilized milk, flavored milk, skim milk, evaporated milk/options <sup>a</sup>	33–45 IU/100 mL
	Voluntary under marketing authorization <sup>c</sup>	Liquid/dried/frozen whole egg/yolk or egg white	Replenishment <sup>b</sup>
		Condensed milk and goat's milk/options	80 IU/100 mL; <i>Maximum</i>
		Milk, goat's milk	80 IU/100 mL
USA	Voluntary	Margarine	1040 IU/100 g
		Milk	331 IU/100 g
		Milk	84 IU/100 g; as vit D <sub>3</sub> ; <i>Maximum</i>
		Edible plant–based beverages and milk alternatives	84 IU/100 g; as vit D <sub>2</sub> <sup>d</sup>
		Yogurt (full fat, low-fat, no-fat)	89 IU/100 g
		Edible plant–based yogurt alternatives	89 IU/100 g; as vit D <sub>2</sub> <sup>d</sup>
		Soy beverage products	89 IU/100 g; as vit D <sub>2</sub> <sup>d</sup>
		Soy-based butter substitute spreads	330 IU/100 g; as vit D <sub>2</sub> <sup>d</sup>
		Cheese and cheese products, excluding cottage cheese, ricotta cheese	81 IU/30 g; as vit D <sub>3</sub>

**TABLE 58.4** Foods fortified with vitamin D in North American and select Nordic countries (excluding infant formula and medical nutrition products).—cont'd

Country	Type of fortification	Foods fortified with vitamin D	Amount of vitamin D added
Finland	Voluntary (but recommendation-based)	Soy-based cheese substitutes and products	270 IU/100 g; as vit D <sub>2</sub> <sup>d</sup>
		Calcium-fortified 100% fruit juices and fruit juices drinks	100 IU/240 mL; as vit D <sub>3</sub>
		Cereal products:	
		enriched farina, ready-to-eat breakfast cereal;	350 IU/100 g
		enriched rice, enriched noodle products, enriched macaroni products	90 IU/100 g
Sweden	Mandatory	Margarine and fat spreads (not butter)	800 IU/100 g
		Fluid milk products: milk, yoghurt, sour milk	40 IU/100 g
		Margarine and fat spreads	780–840 IU/100 g
		Milk: <3% fat, also lactose-free and vegetable-based alternatives	38–44 IU/100 g
Norway	Voluntary (but recommendation-based)	Sour milk: <3% fat, also lactose-free and vegetable-based alternatives	30–44 IU/100 g
		Butter and margarine	400 IU/100 g
		Low-fat milk, also lactose-free	16 IU/100 g

<sup>a</sup>Options include skim milk with added solids, partly skimmed milk with added milk solids, partly skimmed milk, skim milk powder, evaporated skim milk, concentrated skim milk, evaporated partly skim milk, and concentrated partly skimmed milk.

<sup>b</sup>Mandatory if there is a reduction in the vitamin D and/or mineral content to restore the vitamin or mineral nutrient to the amount that was present in the egg product before processing.

<sup>c</sup>Marketing Authorization (MA) for Vitamin D in Milk, Goat's Milk and Margarine: SOR/2021-278 (Canada Gazette, Part II, Volume 156, Number 2 SOR/2021-278 December 29, 2021).

<sup>d</sup>Vitamin D<sub>2</sub> mushroom powder can also be used to achieve these content levels.

Modified from [40,41,55].

policies. In 2003, the Finnish government initiated regulations for the optional vitamin D<sub>3</sub> fortification of milks and yogurt (0.5 µg/100 g) and margarine and spreads (10 µg/100 g) [68]. The resulting increases in vitamin D intakes following implementation of the fortification policy and in serum 25(OH)D concentration pre- and 1-year postimplementation in subsets of the Finnish population, particularly children and teenagers, were assessed and reported [69,70]. As one example, after fortification, the prevalence of winter vitamin D deficiency (serum 25(OH)D < 25 nmol/L) in Finnish men in the Defense Forces (18–28 years) decreased from 19% in January 2003 to 5% in January 2004 [68]. However, Lehtonen-Veromaa et al. [71] found only a modest increase in mean vitamin D intakes (from 4 to 5.4 µg/day) adolescent girls as a result of the fortification policy, and no change in serum 25(OH)D, probably due to low dairy consumption among adolescent girls. In 2010, the National Board of Nutrition doubled the 2003 recommended levels for vitamin D fortification of fluid milk products and spreads [72] (see Table 58.4). Data from the national nutrition survey in Finland (2012) reported vitamin D intakes at 11.1 µg/day among men and 12.8 µg/day among women, with milk and fat spreads contributing up to 60%, depending on age and sex

[73]. A comparison of standardized serum 25(OH)D data from the *Finnish Health* surveys in 2000 (*n* 6134) and 2011 (*n* 4051) shows that the mean serum 25(OH)D increased from 48 nmol/L to 65 nmol/L, and the prevalence of serum 25(OH)D < 30 nmol/L decreased from 12% to <1% [74].

The vitamin D fortification policies in other Nordic countries are summarized in Table 58.4 and were reviewed recently by Itkonen et al. [41]. In brief, in Sweden, milks with a fat content less than 3%, sour milk products, lactose-free products, and vegetable-based alternatives as well as margarines are mandatorily fortified with vitamin D<sub>3</sub>; in Norway, butter, margarine, and some types of low-fat milk are voluntarily fortified with vitamin D, but with lower amounts than Finland and Sweden, whereas in Denmark and Iceland, only a few products are fortified with vitamin D.

### 3.3 Hierarchy of evidence—randomized controlled trials and metaanalyses

Many RCTs of vitamin D—fortified foods have been carried out all over the world in different population groups, using diverse foods and various levels of addition of vitamin D, and a number of systematic reviews

(SR) and metaanalyses of RCTs have confirmed that food fortification is effective in improving vitamin D status [75–79]. The first SR of these trials was carried out by O'Donnell et al. [75], and we updated this analysis in 2012 [76] following publication of several studies around the world. Of 16 separate RCTs in the 2012 SR, all but two showed a significant effect of supplementation on circulating 25(OH)D, which increased by 19.4 nmol/L (95% CI 13.9, 24.9), corresponding to a 1.2 nmol/L (95% CI: 0.72, 1.68) increase for each 1 µg ingested [76]. Twelve RCTs used dairy products as a food source (nine used milk or milk powder). While this is evidence at the highest level that food fortification increases 25(OH)D, both SRs identified overreliance on milk as a weakness in the evidence and recommended considering a more inclusive approach to commodity-based fortification, with careful consideration of the foods used and levels of additions applied [75,76]. In 2018, an SR and metaanalysis of the effect of vitamin D interventions on vitamin D status in children aged 2–18 years included RCTs with fortified foods ( $n = 9$ ; the majority of which were with dairy-based foods), supplements, and bolus injections [77]. The response per 100 IU vitamin D/d was greater with fortified foods than supplements, in trials with a mean baseline serum 25(OH)D < 30 nmol/L and with baseline vitamin D intakes < 100 IU/d. In these analyses, the serum 25(OH)D response to vitamin D intake differed on the basis of baseline status, intakes, and delivery mode, but not age, sex, or latitude.

In 2021, Dunlop and colleagues published a further update and expanded the scope of earlier SRs to include adults and children, to evaluate effects by vitamin D vitamer, and to investigate linear and nonlinear dose–response relationships [78]. This review included 34 studies, which used a broad range of foods in addition to milks, including yogurt, eggs, cheese, fruit juice, biscuits, snack bars, crisp bread, and lavash bread, as well as combinations of foods such as yogurt plus cheese, or egg, yogurt, cheese plus crisp bread. Doses of vitamin D ranged from 3.3 to 100 µg/day (overall mean dose weighted by number of participants was 16.2 µg/day: adults 18.9 µg/day; children 11.8 µg/day). Data from 3930 participants including 2398 adults and 1532 children showed an overall dose–response rate of 1.71 (95% CI 1.24, 2.17) nmol/L per 1 µg of added vitamin D; rates varied by vitamer and adult/child. Thus, with a mean increase of 25(OH)D concentrations of 21.2 nmol/L (95% CI 16.2, 26.2) among participants who received fortified foods, this analysis showed consistent effects of fortifying foods in trials of moderate to high quality. Fig. 58.1 shows nonlinear dose–response effects for all studies combined, adults and children. Using restricted cubic splines, thresholds occurred at 26–29 nmol/L for doses ~20–22 µg/day. When studies

were separated by adults and children, the rate began to slow at a higher dose in adults than children.

The most recent SR identified 11 RCTs with vitamin D–fortified foods with data available for an individual participant data analysis of the response of winter serum 25(OH)D to total vitamin D intake among children and adults and derived dietary requirements for vitamin D intake at prespecified 25(OH)D targets [79]. Of the 11 RCTs, 6 studies used dairy-based foods (of which 5 used a single source (cheese or a cow's milk-based beverage) and 1 used yogurt and cheese), 1 RCT each used bread; eggs; orange juice or biscuits; or milk plus bread; or a combination of four foods (vitamin D–fortified low-fat cheese, yogurt, eggs, and crisp bread). The analysis provided further evidence that food-based approaches to achieve an intake of 12 µg/day could prevent very low vitamin D status (serum 25(OH)D < 30 nmol/L) in the general population [79].

The consistencies between these different SRs are striking: it must now be considered proven that food fortification with vitamin D increases serum 25(OH)D among consumers; that increases in 25(OH)D are nutritionally significant but moderate (i.e., not at risk of excess), and consistent with regular food portions consumed. Fortification of a range of diverse products to maximize the benefit in terms of both consumer coverage and meaningful increases in 25(OH)D for public health is recommended with careful monitoring of doses and quantities consumed through the national dietary surveys supported by current food composition data. The importance of considering dietary diversity has been underscored by evidence from dietary surveys—while vitamin D–fortified milk and related dairy products (including low-fat cheese) are highly effective in raising serum 25(OH)D levels when consumed [75,76,80], and fortification of dairy products beyond fluid milk is technologically feasible [81], evidence that dairy fortification is protective against deficiency on a population basis is present only among high consumers of milk, such as young children. El-Hayek et al. [82] showed that 25(OH)D concentrations in preschool children in Montreal increased in a step-wise manner by tertile of milk intake. Among the wider population, with increased variability in milk consumption, the situation becomes more complex. In the United States, Newman et al. [46] presented the cumulative proportions of vitamin D intakes from naturally occurring food sources only, plus enrichment/fortification, plus dietary supplements in individuals aged >2 years in the NHANES 2009–12. The mean intake of 1.6 µg/day from natural food sources increased to 5.4 µg/day when enrichment/fortification was accounted for. Increases were highest among young children (1.3–7.3 µg/day in 2–8 year olds) due to their high milk intakes, dropping to an increment of 1.3–5.7 µg/

A.

**FIGURE 58.1** Dose-response data for the change in circulating 25(OH)D concentrations in randomized controlled trials of vitamin D

fortified and biofortified foods. Restricted cubic spline models with three knots at vitamin D doses of 0, 5 and 20  $\mu\text{g}/\text{day}$  for: (A) Overall (34 publications, 40 data points); (B) adults (27 publications, 31 data points) and (C) children (7 publications, nine data points) are shown. Modified from Ref. [78], with author's permission.

day in 9- to 18-year-olds [46]. Likewise, in Canada, mean vitamin D intakes arising from milk products in those aged 9 years and over were in the range 2.5–3  $\mu\text{g}/\text{day}$ , contributing 49.1% to the mean daily intake of vitamin D [57]. However, the prevalence of inadequate vitamin D intakes remains very high in both the United States and Canada [46,48,55–57], highlighting variable rates of milk consumption.

Even with mandatory fortification, >80% have vitamin D intakes <10  $\mu\text{g}/\text{day}$  in Canada (>94% when vitamin D intakes from food and beverages alone were considered [48]); however, modeling of the 2004 Canadian Community Health Survey 2.2 data ( $n = 34,381$ ) showed that this prevalence could be decreased to <50% in all groups with increased vitamin D levels in milk and the addition of vitamin D to cheese and yogurt at various levels [50]. In countries where fortification of milk is voluntary and the uptake is far less than in the United States, the impact of vitamin D-fortified milk and dairy on adequacy of vitamin D intake is low. Using data from recent national nutrition surveys in the United Kingdom and Ireland as two exemplars, it is evident that in general the percentage contribution that milk and dairy makes to the mean daily intake of vitamin D are low ( $\leq 7\%$ ) for those aged 11 years upward in both populations, while fat spreads contribute about 16% and 8% in the United Kingdom and Ireland, respectively [37,83]. About 17% and 38% of Irish adults, aged 18–64 years, used vitamin D-fortified milks and fat spreads, respectively, in the most recent national dietary survey of 2010 [37]. Interestingly, survey data collected 10 years previously in Ireland, when fortified milk was a rare product, showed that only 5% of adults were consumers—no doubt this figure will continue to increase over time [37]. Currently, with market penetrance and current ad hoc/nonstrategic levels of addition, it is not surprising to find that in Europe in general the intake of vitamin D from voluntary fortified foods has been reported as low [84].

The problem of fortifying a single staple, e.g., milk, or focusing on a commodity sector such as dairy, is that it does not increase the vitamin D supply in non- or low consumers [40]. Blacks in the United States have lower intakes of vitamin D than whites (9.5 vs. 14.2  $\mu\text{g}/\text{day}$ , respectively, [47]) due to their consumption of less milk, ready-to-eat cereals, and dietary supplements [56]. In addition, nondairy plant-based beverages, also known as plant milks, some of which are not fortified

with vitamin D, are an increasingly popular product category and may displace some vitamin D–fortified dairy milk within the food chain for some populations.

Thus, while acknowledging the valuable contribution fortified milk makes to vitamin D intakes among consumers, particularly in children, and the continued need for fortification of milk and other dairy products, additional strategic approaches to fortification, including biofortification, of a wider range of foods, have the potential to increase vitamin D intakes in the population [23,40]. Beyond dairy-related foods and plant-based alternatives, fruit juices and certain cereal products (but not wheat) can be fortified with vitamin D in the United States (but not by law in Canada) [55] (see Table 58.4). Not surprisingly, ready-to-eat cereals (about 75% are fortified [67]) together with milk are the predominant food sources of vitamin D in the United States [55,56].

#### 4. Consideration of other vitamin D–fortified foods

The WHO-FAO have suggested that in many settings, food fortification can be a very affordable way of correcting inadequate micronutrient intakes, and more often than not, the main challenge is finding a suitable industrially manufactured food vehicle that is consumed in sufficient amounts by the population at risk [52]. The cost and choice of food vehicle(s) are also important more considerations in terms of trying to ensure equality of access to these foods within the population. In the context of adapting the global food systems to minimize environmental impacts, with emphasis on increased consumption of plant-based foods and reductions in dairy and ruminant meat [85], the fortification of non–animal-derived foods, such as wheat and other cereals, bread, edible oils, and possibly biofortification of fungi and baker's yeast, with vitamin D may be of increasing importance for nutrition security.

In terms of diversification of food fortification beyond milk, experimental evidence from Denmark [86] in the form of data from a large, well-characterized RCT showed effects of vitamin D–fortified milk and bread on serum 25(OH)D in 201 families ( $n = 782$  children and adults, aged 4–60 years). The groups randomized to vitamin D–unfortified and vitamin D–fortified foods had median intakes of vitamin D of 2.2 and 9.6  $\mu\text{g}/\text{day}$ , respectively, over the 6 months of the study. By the end of the study period, none and 16% in the fortified food group had serum 25(OH)D levels below 25 and 50 nmol/L, respectively, with the corresponding prevalence estimates for the group receiving unfortified foods at 12% and 65%

[86]. With no evidence of an adverse effect, this is compelling evidence for efficacy of a two-strand/multiapproach to low-dose fortification of commodity foods.

To complement priority evidence of effectiveness of food fortification approaches from RCTs that evaluate their impact on reducing the prevalence of vitamin D deficiency in the populations studied [4], dietary modeling analysis, based on data from nationally representative dietary surveys, can provide *in silico* projections of how these food interventions may impact on the degree of vitamin D intake inadequacy in the population [37]. For example, Allen et al. [87] modeled the impact of a number of simulated vitamin D fortification scenarios, with milk and wheat flour identified as primary fortification vehicles, on vitamin D intake distribution within the first 2 years (2008–10) of the UK National Diet and Nutrition Survey rolling program ( $n = 2127$  individuals). At a simulated fortification of 10  $\mu\text{g}$  vitamin D/100 g wheat flour, the proportion of at-risk groups estimated to have vitamin D intakes below the UK Reference Nutrient Intake were reduced from 93% to 50% [87]. Interestingly, the simulation of the fortification of wheat flour at this concentration was more effective than that of the fortification of milk (at concentrations between 0.25 and 7  $\mu\text{g}$  vitamin D/100 L milk) or fortification of milk and flour combined. The authors suggested that vitamin D fortification of wheat flour could be a viable option for safely improving vitamin D intakes and the status of the UK population groups at risk of deficiency [87]. Finally, a similar modeling exercise was undertaken to determine the best foods for potential vitamin D food fortification for adults  $\geq 50$  years of age in Ireland [88]. Bread and milk, as the most frequently consumed foods across all meals, were targeted for the data modeling exercise. The modeling showed that fortifying milk (generally all with 1.5  $\mu\text{g}/100$  mL, but some milks currently fortified with 2.5  $\mu\text{g}/100$  mL were retained in the model) or bread (all with 5  $\mu\text{g}/100$  g) resulted in 31% and 56% of individuals, respectively, meeting a target intake of 10  $\mu\text{g}/\text{day}$ ; however, fortifying both simultaneously resulted in 71% meeting this target intake.

More globally, Babu and Calvo [89] suggested that fortification of wheat flour may have potential to alleviate vitamin D deficiency in countries where pasteurized milk is not widely consumed. Currently, four countries (Jordan, Mongolia, Palestine, and Chile) have mandatory fortification of wheat flour with vitamin D, whereas four more have voluntary fortification [90]. Nine countries mandate the fortification of edible oils with vitamin D, while an additional four countries allow voluntary fortification of oil [90]. The majority of these countries are either in Asia or Africa.

#### 4.1 Additional considerations in relation to forms of vitamin D and addition amounts for traditional fortification

As discussed before, while recent data suggest that the levels of vitamin D added to food would need to be high enough so as to ensure dietary requirements are met and health outcomes optimized, knowledge of which are the most effective forms of vitamin D to use in some of these preventative approaches is also important. The following section will briefly consider the main forms of vitamin D that could be used in terms of fortification of food.

#### 4.2 Vitamin D<sub>2</sub> versus vitamin D<sub>3</sub>

While vitamin D<sub>2</sub> and D<sub>3</sub> [the two main food-derived forms (although vitamin D<sub>2</sub> only occurs in only a minority of foods and generally at very low levels naturally) and those used in vitamin D supplements] could be used as a fortificant, there is still ongoing debate in relation to the relative efficacy of these two forms of vitamin D in terms of raising serum total 25(OH)D (i.e., concentration of serum 25(OH)D<sub>2</sub> plus 25(OH)D<sub>3</sub>) [33,91–93]. Some, but not all, studies suggest that the response of serum total 25(OH)D to increased intake of supplemental vitamin D<sub>2</sub> is lower than that of supplemental vitamin D<sub>3</sub> (reviewed elsewhere [13,14,32,33,91–93]). Houghton and Vieth [93], in their review of the available data and evidence, provide a very succinct overview of several biologically plausible mechanisms that could contribute to the greater capacity of vitamin D<sub>3</sub> over vitamin D<sub>2</sub> to maintain higher 25(OH)D concentrations over time. They suggest when the data and findings are taken together, the most plausible explanations for the greater bioefficacy of vitamin D<sub>3</sub> are conceivably due to the higher affinities of vitamin D<sub>3</sub> and its metabolites than vitamin D<sub>2</sub> for hepatic 25-hydroxylase, vitamin D–binding protein, and the vitamin D receptor and because vitamin D<sub>3</sub> is not directly metabolized to 24-hydroxyvitamin D as is vitamin D<sub>2</sub> [93]. A lower response of serum total 25(OH)D with supplemental vitamin D<sub>2</sub> may also relate to enhanced catabolism of 25(OH)D<sub>3</sub>, despite an increase in serum 25(OH)D<sub>2</sub> ([94], and see below under UVB-enhanced mushrooms in Section 5). However, it is important to stress that both forms of vitamin D unquestionably elevate serum total 25(OH)D as evidenced in several systematic reviews [32,33,92] and the fact that vitamin D<sub>2</sub> has been used as a pharmaceutical preparation in the United States for decades [93]. Thus, both forms could be used as a food fortificant, especially in countries where non-animal-derived sources may be preferred. As mentioned before, the FDA has approved use of vitamin D<sub>2</sub> in milk alternatives and yogurts made from edible plants [65].

#### 4.3 25-Hydroxyvitamin D metabolites

While the major metabolite of vitamin D with biological activity is 1,25-dihydroxyvitamin D [1,25(OH)<sub>2</sub>D] [14], and there is presence of minor amounts of this metabolite in some foods of animal origin (as is the case with 25(OH)D [91]; and see below); 1,25(OH)<sub>2</sub>D, and its analogs, are only used for pharmacological purposes and not typically used in healthy people to improve vitamin D status.

While 25(OH)D has also been used for pharmacological purposes, it is present in certain foods of animal origin, such as meat, offal, eggs, and to a lesser extent fish (for reviews, see Refs. [91,95]). However, some of this contribution stems from the fact that the UK (and others such as Danish and Swiss) food composition tables suggest that 25(OH)D may possess up to five times the activity of native vitamin D<sub>3</sub> in food [25,96,97]. The “total vitamin D activity” of foods in such food compositional data accounts for not only the vitamin D content of the food but also the content of the 25(OH)D multiplied by the factor of 5. The US food composition database has recently reported 25(OH)D<sub>3</sub> data for beef and a limited number of other foods [98], but does not include these in the total vitamin D values for these foods. Taylor et al. [99] performed modeling to include overall food-derived 25-hydroxyvitamin D in intake estimates for US adults, which showed that there was a potentially meaningful increase (1.7–2.9 µg or 15%–30% of the EAR) in vitamin D intake estimates. However, there is some debate around use of this factor of 5, with alternate suggested factors ranging from 1 to 9 (for reviews, see Refs. [91,95,100]). A relatively recent review of nine available RCTs comparing physiologic doses of oral vitamin D<sub>3</sub> with oral 25(OH)D<sub>3</sub> concluded that 25(OH)D<sub>3</sub> was 3.2-fold more potent than oral vitamin D<sub>3</sub> [101]. Use of synthetic 25-hydroxyvitamin D (calcidiol monohydrate) as a food supplement (supplying a maximum daily intake is 10 µg/day) has very recently been approved by EFSA for individuals ≥11 years old, including pregnant and lactating women [102]. Use of 25(OH)D in animal feeds for certain species is permitted in Europe and the United States [103,104], and this can increase the content of 25-hydroxyvitamin D<sub>3</sub> in the human food chain (see biofortified foods in Section 5).

Whether vitamin D<sub>3</sub> or D<sub>2</sub>, and/or possibly 25-hydroxyvitamin D<sub>3</sub> in the future, is the fortificant of choice depending on food type and indeed consumer group, the levels of addition need to be cognizant of the tolerable upper intake levels (ULs) for vitamin D ([14,105] and see Section 6). As highlighted by the WHO-FAO, cost of the fortificant ingredient is also a consideration [52]. For food business, the cost of fortification is influenced by (1) the type of fortificant; (2) the point at which it is added to the product; (3) the need

for quality control; (4) the volumes being purchased; (5) the product category, and (6) the profit margin between and within different food categories [106]. For the breakfast cereal industry, vitamin D is one of the most expensive fortificants currently added because of the cost of the technologies required to add the vitamin, rather than the cost of the vitamin per se. However, the cost will be dependent on the nature of the technology needed and whether it is D<sub>2</sub> or D<sub>3</sub> that is added. For example, the cost of adding vitamin D is less for dairy-based foods and so is not perceived to be a major economic hurdle [106]. While overall, adding extra vitamin D into foods will incur a cost, for the most part this is likely to be low, at least for the consumer. For example, flour fortification with vitamin D at 550 IU [13.7 µg]/kg of flour only adds a very modest cost of US\$0.04–0.05 per metric ton of flour (Personal communication Quentin Johnson, Food Fortification Initiative, [www.ffinetwork.org](http://www.ffinetwork.org)). In the case of the 25(OH)D biofortification of eggs, the cost per dozen eggs was deemed minimal (approximately 0.1 p per dozen eggs) [106].

## 5. Vitamin D—biofortified foods

While traditional fortification practices in which exogenous vitamin D is added to dairy and other foodstuffs will continue to be an important approach for increasing vitamin D in the food supply, the use of vitamin D “biofortified” (also referred to as “bioaddition” [55]) foods has received increasing attention over the past decade [40,54]. In this approach, the animal produce (such as, for example, cultured/farmed fish, beef, pork, lamb, chicken, and eggs) could have increased vitamin D and/or 25-hydroxyvitamin D contents by virtue of addition of vitamin D and/or 25-hydroxyvitamin D (where permissible) to the respective fish, livestock, or poultry feeds. In biofortification, the vitamin D compounds in the resulting foodstuffs from the animals will be incorporated in a manner similar to native vitamin D and, unlike in traditional fortification, will be under some degree of biological regulatory control mechanisms in the animal. An important concept in relation to vitamin D biofortification is that it can increase the “total vitamin D activity” (as discussed before) of the biofortified foods. Improving the total vitamin D activity of these foods may be of consequence not only to the population as a whole, but in particular, for low or nonconsumers of vitamin D—fortified dairy products and also ethnic subgroups. For example, in the Irish adult diet, the meat, fish, egg food groups, even without biofortification, collectively contribute ~40% to the mean daily intake of vitamin D [45]. Van Horn et al. [107] reported that in US adolescent girls, while the meat and bean food group contributed ~4% to the mean daily intake of vitamin D

in white girls, it contributed 26% to the mean daily intake of vitamin D in African American girls. The possibility of enhancing the vitamin D activity of meat, eggs, and other relevant foods further by biofortification and its potential impact on population and ethnic subgroup intake estimates is of significant public health nutrition relevance.

The most researched vitamin D—biofortified food to date is, without doubt, eggs. In the past two decades, there have been several reports illustrating that the vitamin D<sub>3</sub> content of eggs can be significantly increased by the greater addition of vitamin D<sub>3</sub> to the feed of hens [108–113]; however, several of these studies [109,110,112,113] used levels of inclusion above the upper allowable level for feeds in Europe (3000 IU/kg diet [114]). Addition of commercially available 25-hydroxyvitamin D<sub>3</sub> to the diet of hens has also been shown to increase egg 25-hydroxyvitamin D<sub>3</sub> content [111–113], albeit two studies [111,112] used 25-hydroxyvitamin D<sub>3</sub> at levels above the upper allowable level for the United States and Europe (0.069 and 0.080 mg/kg diet, respectively [103,104]). Many of these studies were predominantly focused on the effect that higher levels of vitamin D compounds in animal feeds may have on the welfare of the animal itself or the quality of their produce (e.g., egg shell strength, laying rate) rather than its impact on the vitamin D activity of the resulting eggs and their potential to improve the vitamin D status of humans. The WHO-FAO have suggested that access to and use of fortificants that are well absorbed yet do not affect the sensory properties of foods is important [52]. In terms of producing eggs that would be acceptable for human consumption, addition of vitamin D and/or 25-hydroxyvitamin D<sub>3</sub> to feedstuffs at levels adhering to the maximum allowable EU regulation [103,114] has been shown to result in eggs with increased vitamin D activity (providing ~4–5 µg/egg), and, importantly, no deterioration of consumer acceptability of the biofortified eggs compared with usual eggs [106,115]. Thus, such vitamin D—biofortified eggs could supply close to half the EAR for vitamin D. As mentioned before, evidence of effectiveness of food fortification approaches from RCTs, which evaluate their impact on reducing the prevalence of vitamin D deficiency in the populations studied, is a key priority in terms of the evidence base [4]. In that context, we have shown in a winter-based RCT of older adults (*n* = 55) that weekly consumption of seven vitamin D—biofortified eggs, produced by hens provided with feed containing either vitamin D<sub>3</sub> or 25-hydroxyvitamin D<sub>3</sub> at the allowable maximum content, prevented the typical decline in serum 25(OH)D concentration during winter and any incidence of vitamin D deficiency [115]. The control group in the study, who were requested to consume weekly up to a maximum of two commercially available eggs, had a significant

decline in serum 25(OH)D over the 8 weeks of winter, and 22% had serum 25(OH)D < 25 nmol/L at endpoint [115]. From a dietary guideline perspective, the general population can include up to seven eggs a week in their diet [116], and our RCT showed no difference in serum total cholesterol among control and vitamin D—biofortified egg groups [115]. Recently, another RCT of egg consumption on vitamin D status added further support to their utility as a means of maintaining serum 25(OH)D during winter. In a 12-week, Australian-based RCT, adults (aged 25–40 years) were randomized to consume 2, 7, or 12 commercially available eggs per week [117]. This translated into weekly vitamin D doses of 10.4, 36.3, and 62.2 µg, respectively. Mean serum 25(OH)D did not change significantly in either the 7 or 12 eggs/week group, but decreased by 28.6 nmol/L in the control group after the 12 weeks of autumn/winter [117]. Serum lipids did not differ between the groups. The authors concluded that consuming seven eggs per week for 12 weeks was effective for attenuating the wintertime decline in vitamin D status in young Australian adults, with 12 eggs per week not providing any additional benefits [117].

The feasibility of producing other vitamin D—biofortified animal-based foods (such as beef, pork, and cultured/farmed fish) has been demonstrated, with variable levels of improvement in vitamin D content over nonbiofortified equivalent foods (see

Table 58.5). In relation to biofortified meats, the increments in vitamin D content are relatively modest [118–121], and this is likely due to the fact that the transfer of additional vitamin D in feedstuffs to tissues is subject to biological regulatory control mechanisms in the animal. Data from RCTs investigating the impact of consumption of vitamin D—biofortified meats on vitamin D status are as yet lacking. The UK food composition database suggests that the flesh (fillet) of farmed and wild salmon has 4.7 and 8.6 µg/100 g, respectively [25]. Graff et al. recently compared the impact of consumption of biofortified versus control salmon (fish feed had 2.6–2.9 mg vitamin D<sub>3</sub>/kg vs. 0.23 mg vitamin D<sub>3</sub>/kg, respectively) on vitamin D status in a 12-week intervention trial in healthy postmenopausal women [122]. The women consumed 150 g of salmon two times per week, with the vitamin D—biofortified and control groups consuming the vitamin D daily equivalent of 16 µg/day versus 3.9 µg/day, respectively, from the salmon. There was a significant increase in mean serum 25(OH)D of ~12 nmol/L in the vitamin D—biofortified groups versus a nonsignificant 1.3 nmol/L decline in the low vitamin D group over the 12-week intervention [122]. It should be noted, however, that the level of addition of vitamin D<sub>3</sub> to the fish feed exceeded that allowable currently by European legislation (1.5 mg/kg diet [123]). Following the demonstration of efficacy of some of these vitamin D—biofortified foods, at least, on

Modified from Ref. [53].

response of serum 25(OH)D in RCT settings, as mentioned before, dietary modeling analysis based on data from nationally representative dietary surveys within the EC-funded ODIN project (Food-based solutions for optimal vitamin D nutrition and health through the life cycle, <https://cordis.europa.eu/project/id/613977>) has provided in silico projections of how these food interventions may impact on the degree of vitamin D intake inadequacy in the population. For example, a combination of biofortified foods (such as eggs, beef, and pork) together with fortified milk and cheese allowed for projected mean and median intakes close to the EAR to be achieved, without increasing the risk of excessive intakes [106]. In line with these findings, a recent dietary modeling analysis of the impact of vitamin D biofortification of pork and pork products on population vitamin D intakes in the UK [124]. Using four theoretical dietary scenarios, where the vitamin D content was increased 50%, 100%, 150%, and 200% over that present normally, the predicted increases in vitamin D intake in the population were 4.9%, 10.1%, 15.0%, and 19.8%, respectively. However, in quantitative terms this means at the highest increment (200%), the mean vitamin D intake in the population increased from 2.47 to 2.96 µg/day [124].

Finally, biofortification with vitamin D could also embrace the practice of UV irradiation of mushrooms and baker's yeast, which have been shown to stimulate their endogenous vitamin D<sub>2</sub> content. These foods may be a useful strategy to increase vitamin D intakes for vegetarians or those who do not consume meat or foods of animal origin for cultural reasons, but also for the wider population, particularly in the case of bread, as mentioned before and particularly in the context of more flexitarian-type diets of the future. From a technological perspective, UV-irradiated foods can be

produced with anything from low to very high levels of vitamin D<sub>2</sub> [125]. However, in terms of RCT-based evidence of effectiveness, a recent 8-week RCT within the ODIN project [126], investigated the bioavailability of D<sub>2</sub> from UV-irradiated yeast present in bread in healthy 20- to 37-year-old women ( $n = 33$ ) in Helsinki (60°N) during winter. Four study groups were given different study products, either a placebo pill and regular bread (providing 0 µg vitamin D<sub>2</sub> or D<sub>3</sub> per day); a vitamin D<sub>2</sub> supplement and regular bread (providing 25 µg vitamin D<sub>2</sub> per day); a vitamin D<sub>3</sub> supplement and regular bread (providing 25 µg vitamin D<sub>3</sub>/d); or a placebo pill and vitamin D<sub>2</sub>-fortified bread (made with UV yeast) (providing 25 µg D<sub>2</sub>/d). Serum 25(OH)D concentration was measured at baseline, midpoint (week 4), and endpoint (week 8). The study showed that serum 25(OH)D concentrations did not change in those consuming UV yeast—vitamin D<sub>2</sub>-fortified bread only. Those receiving supplemental vitamin D (as either D<sub>3</sub> or D<sub>2</sub>) together with regular bread had appreciable increases [126]. Analysis of the UV yeast bread following baking confirmed that it contained the 25 µg vitamin D<sub>2</sub>, which suggests that vitamin D<sub>2</sub> from UV-irradiated yeast in bread, despite being present postbaking, is not currently bioavailable in humans. EFSA has approved treatment with UV radiation of bread, after the baking process is complete [127]. This allows the ergosterol, which is present in bread as a result of yeast fermentation, to be converted to vitamin D<sub>2</sub>. The bioavailability of the vitamin D<sub>2</sub> from this novel bread has not been examined thus far.

The RCT data demonstrating that the vitamin D<sub>2</sub> in UV-treated mushrooms can increase vitamin D status of consumers have been quite mixed, and accordingly, we undertook a systematic review and metaanalysis of the impact of UV-exposed mushrooms on serum

25(OH)D response in these RCTs [128]. Our structured search yielded six RCTs meeting our inclusion criteria, and a metaanalysis of these six RCTs showed serum 25(OH)D was not significantly increased ( $P = .12$ ) by UV-exposed mushrooms, but there was high heterogeneity ( $I^2 = 87\%$ ). Including only the three European-based RCTs (mean baseline 25(OH)D, 38.6 nmol/L), serum 25(OH)D was increased significantly by UV-exposed mushrooms, whereas there was no significant effect in the 3 US-based RCTs [ $P = .83$ ; mean baseline 25(OH)D: 81.5 nmol/L] [128]. Analysis of serum 25(OH)D<sub>2</sub> and serum 25(OH)D<sub>3</sub> ( $n = 5$  RCTs) revealed a statistically significant increase and decrease after supplementation with UV-exposed mushrooms (weighted mean differences of 20.6 nmol/L and  $-13.3$  nmol/L, respectively:  $P < .001$ ) [128]. Thus, consumption of UV-exposed mushrooms may increase serum 25(OH)D when baseline vitamin D status is low via an increase in 25(OH)D<sub>2</sub> and despite a concomitant but relatively smaller reduction in 25(OH)D<sub>3</sub>. However, when baseline vitamin D status is high, the increase in 25(OH)D<sub>2</sub> and a relatively similar reduction in 25(OH)D<sub>3</sub> explain the lack of effect on serum 25(OH)D. Since this systematic review, two additional RCTs with UV-exposed mushrooms have been published [129,130]. One was an Australian-based, 6-month double-blind, RCT on the effects of supplemental vitamin D<sub>3</sub> (15 µg/day), vitamin D<sub>2</sub> (15 µg/day)-enriched mushroom, standard mushroom, and placebo (all as capsules) on cognition and mood in 436 healthy older adults ( $\geq 60$  years). The study was conducted from April to October (Autumn–Winter) over two successive years. However, compared with placebo ( $-12.2$  nmol/L), the decline in total 25(OH)D in the vitamin D<sub>2</sub>–mushroom group over the 24 weeks of intervention was smaller ( $-7.9$  nmol/L) and slower, while the supplemental vitamin D<sub>3</sub> group increased ( $+4.4$  nmol/L) [129]. This study also showed that in relation to serum 25(OH)D<sub>3</sub>, which declined in the placebo group over the course of the 24 weeks of intervention, it was more pronounced and faster in the vitamin D<sub>2</sub>–mushroom group, and this was evident even when subjects were stratified by baseline total serum 25(OH)D  $< \text{or } \geq 75$  nmol/L [129].

The second RCT was based in the United Kingdom, and in this study, 28 recreationally active, healthy adults were randomized to receive 25-µg encapsulated mushroom-derived vitamin D<sub>2</sub>, matched-dose encapsulated vitamin D<sub>3</sub>, or placebo for 12 weeks (months of the year not reported) [130]. Over the 12 weeks of intervention, the mean total serum 25(OH)D in the group receiving vitamin D<sub>3</sub> capsules increased from 46 to 88 nmol/L, due to increases in serum 25(OH)D<sub>3</sub>, whereas in the placebo group, total serum 25(OH)D remained relatively stable over the period. In contrast, the mushroom–vitamin D<sub>2</sub> group had a significant

increase in mean serum 25(OH)D<sub>2</sub> over the 12 weeks (from 7.0 to 31.4 nmol/L), but serum 25(OH)D<sub>3</sub> decreased from 50.8 to 34.4 nmol/L over the same period [130]. Thus, total 25(OH)D remained unchanged throughout the 12-week period. The FDA has an approved list of foods in which vitamin D<sub>2</sub>–mushroom powder may be used as a source of vitamin D<sub>2</sub> [131].

Artificial UV light technology has also recently been shown to increase the vitamin D<sub>3</sub> content of exposed milk during processing to enhance shelf life, a process approved by EFSA [132]. To our knowledge, no clinical studies have been carried out using this product.

## 6. Safety considerations and prerequisite data required prior to initiating public health measures

Nutrient intake, unlike substances such as drugs or chemical toxicants where there is zero to minimal background exposure, can pose a dual risk, due to either inadequate or excessive consumption. Concentrations of circulating 25(OH)D increase in response to ingestion of vitamin D and reach a steady state after 6–8 weeks [133,134]. If the dose of vitamin D increases, circulating 25(OH)D will continue to rise. High serum 25(OH)D concentrations ( $>220$  nmol/L) may lead to hypercalcemia [135], defined as a serum calcium  $>2.63$ – $2.75$  mmol/L (as defined by individual laboratory reference ranges), and is mainly related to primary hyperparathyroidism or malignancy, but can also be induced by very high calcium or vitamin D intakes. Vitamin D ingested orally is relatively safe, and toxicity is not apparent at doses up to 250 µg/day [14,105]. However, the International Agency for Research on Cancer [136], among others, has pointed out that there are no data on the health hazards of maintaining high serum 25(OH)D in healthy persons over long periods and urged caution to be mindful of past experiences with other compounds (e.g., some antioxidants and hormone replacement therapies) that showed serious adverse effects when chronic high-dose supplements were used. Over and above the risk of hypercalcemia, reports of U- and reverse J-shaped distributions for serum 25(OH)D and adverse consequences, including all-cause mortality, cardiovascular disease risk, PTH suppression, and fetal growth restriction [4,14,137], are being considered on an ongoing basis. Safety data from the ODIN project show that the prevalence of high serum 25(OH)D (i.e.,  $>125$  nmol/L) was only 0.1% for fortified foods compared with 9.4% among the participants who ingested vitamin D supplements [138].

The ULs for vitamin D from the IOM [14] and the EFSA [105,139] were established on the basis of minimizing the risk of hypercalcemia and using evidence from vitamin D supplementation studies. An additional cautionary note was introduced due to the lack of

empirical data on the potential adverse effects of chronic high consumption of vitamin D producing a sustained serum 25(OH)D above  $\sim 125$ – $150$  nmol/L. Thus, to maximize public health protection, an uncertainty factor of 1.2–2 was applied, and both agencies assigned a UL for vitamin D of  $100\text{ }\mu\text{g/day}$  for all adults including pregnant and lactating women [14,105]. The ULs proposed by both organizations were generally similar with slight variation among children. In 2012, the EFSA [105] set a UL for vitamin D of  $25\text{ }\mu\text{g/day}$  for infants up to 1 year;  $50\text{ }\mu\text{g/day}$  from 1 to 10 years, and  $100\text{ }\mu\text{g/day}$  for children aged 11 years and over. The IOM [14] scaled the UL as follows:  $25\text{ }\mu\text{g/day}$  for infants aged 1–6 months, increasing to  $38\text{ }\mu\text{g/day}$  up to 12 months,  $63\text{ }\mu\text{g/day}$  for 1–3 year olds, and  $75\text{ }\mu\text{g/day}$  from 4 to 8 years. The UL for children aged 9 years and over is the same as adults, at  $100\text{ }\mu\text{g/day}$ . Since the IOM and EFSA published their opinions, Gallo et al. [140] reported a randomized controlled dose–response trial in infants in Montreal to test the efficacy of vitamin D at 10, 20, 30, and  $40\text{ }\mu\text{g/day}$  in maintaining 25(OH)D concentrations  $>75$  nmol/L over an 11-month period. By 3 months, 55% of infants in the  $10\text{ }\mu\text{g/day}$  group and 80%–100% of those in the higher doses had a serum 25(OH)D concentration  $\geq 75$  nmol/L. The authors discontinued the  $40\text{ }\mu\text{g/day}$  dose because almost all infants on this dose had serum 25(OH)D concentrations  $\geq 250$  nmol/L by 3 months of age. In addition to valuable information on the nutritional requirement for vitamin D in infancy, these data provided evidence to underpin the lower EFSA UL of  $25\text{ }\mu\text{g/day}$  for infants from 6 to 12 months set in 2012 [105]. Notwithstanding these data, the EFSA revised its UL for infants aged 6–12 months to  $35\text{ }\mu\text{g/day}$  in 2018 [139]. In Europe, the EFSA has recently issued a draft scientific opinion on the Tolerable Upper Intake Level for vitamin D in all age-groups except infants, with the public consultation on this due to close on 5th June 2023 [141]. The proposed ULs for vitamin D in this draft opinion remain unchanged from those set in 2012 (see above).

In terms of monitoring the safety of any dietary strategies to increase vitamin D intakes in the population, the main requirement is that intakes at the 97.5th percentile of the distribution do not exceed the UL for a specified age group. Food-based strategies for vitamin D fortification by nutrient addition or biofortification are designed to increase habitual vitamin D intakes in the population, operate principally on the basis of providing a modest increment in vitamin D across a range of foods to accommodate the diverse dietary practices in modern society. The objective is to change the *shape* of the vitamin D intake distribution to ensure that average and median intakes are at least  $10\text{ }\mu\text{g/day}$ , without increasing the intake at the 97.5th percentile. Data

requirements to assess the risk of exceeding the UL are population-based dietary surveys of representative samples of individuals that include vitamin D intakes from the base diet, from fortified foods and from nutritional supplements. Quality survey data collected on an individual basis, supported by up to date food composition data, can therefore be used in modeling experiments to test the likely effects, within specified age groups, of making changes to the vitamin D supply in the food chain. In particular, modifications to commodity items, such as milk and bread, should have thorough population-based modeling data to support a risk–benefit analysis prior to implementation.

## 7. Conclusions

There is widespread acknowledgment of the presence of very low vitamin D status in the community and the pressing need to address this ongoing problem. Currently, the major regulatory authorities recommend vitamin D intakes in the order of  $10$ – $20\text{ }\mu\text{g/day}$ , depending on age and whether the serum 25(OH)D target is  $\geq 25$  or  $\geq 50$  nmol/L. The current dietary supply of vitamin D makes it unfeasible for the vast majority of children and adults to meet recommended intake targets. Evidence is now overwhelming, from multiple strands including RCTs, systematic reviews, and meta-analyses of RCTs among adults and children across the globe, that vitamin D fortification is effective at increasing vitamin D status. National surveys and case studies of countries that have implemented fortification strategies with appropriate monitoring have demonstrated that targeted approaches can bridge the gap between current and recommended intakes of vitamin D, without increasing the risk of excessive intakes. Traditional food vehicles, such as milk, are only one element of a broader approach to include vitamin D enhancement in a range of products for the benefit of the wider community. There is now trial evidence for the effectiveness and safety of multistrand approaches, as, taken together, small increments in the vitamin D content of commonly consumed foods deliver meaningful increases across the intake distribution. For example, eggs show excellent potential for providing a significant quantity of vitamin D, fortified breads can provide additional vitamin D, and there are emerging data for vitamin D<sub>2</sub> enhancement of mushrooms for vegetarian consumers.

Further research is required on the potential role of foods such as meats, fish, UV-irradiated yeast and breads, and oils, promising potential vehicles that require further work to ensure reproducibility and stability of vitamin D levels achieved. Longer-term community-based intervention studies with standardized approaches to trial design,

ensuring data collection of relevance to public health, e.g., safety, are also required, particularly using combinations of fortified foods among participants of different ages. Wider uptake of reference measurement procedures for analysis of serum 25(OH)D and ongoing food composition analysis for vitamin D and 25(OH)D in foods supported by food-based standard reference materials are also key cornerstones of integrated technological, experimental, and modeling efforts to improve vitamin D intakes and prevent nutritional deficiency. Finally, while scientists have known for many years that fortifying food can prevent vitamin D deficiency, to date, insufficient cooperation between scientists and the public, government agencies, policy-makers, and the industry means that knowledge has not translated to action in most countries. Development and implementation of policy requires more than scientific evidence. New approaches to code-signing nutrition policy frameworks are required for knowledge translation.

## 8. Summary points

- Due to insufficient UVB exposure, low vitamin D status is widespread in the community, affecting many millions of people of all ages.
- It is not feasible for most populations to meet their vitamin D requirement from dietary sources, as vitamin D is low in the food supply.
- For the majority of the population from infancy upward, there are multiple strands of evidence from national nutrition and health surveys to RCTs to show that food fortification represents the most efficient and safest opportunity to increase vitamin D intakes across the population.
- Within specific regulatory contexts, vitamin D<sub>2</sub>, vitamin D<sub>3</sub>, and 25-hydroxyvitamin D can be used as food fortificants, with varying levels of efficacy in terms of their ability to increase serum 25(OH)D in consumers of the fortified, or biofortified foods.
- Multistrand approaches to food fortification should be considered, as, taken together, small increments in the vitamin D content of commonly consumed foods can deliver meaningful increases across the population intake distribution.

# Bariatric surgery, vitamin D, and bone loss

Tiffany Y. Kim<sup>1,2</sup> and Anne L. Schafer<sup>1,2</sup>

<sup>1</sup>University of California, San Francisco, CA, United States <sup>2</sup>San Francisco Veterans Affairs Health Care System, San Francisco, CA, United States

## OBJECTIVES

- Recognize the indications for bariatric surgery and the most commonly performed bariatric procedures.
- Understand the effects of bariatric surgery on bone turnover, bone mass, bone microstructure, and fracture risk.
- Discuss potential mechanisms for skeletal effects after bariatric surgery.
- Explain the effects of bariatric surgery on vitamin D status and an approach to vitamin D supplementation.
- Understand the effects of Roux-en-Y gastric bypass and sleeve gastrectomy on intestinal calcium absorption.
- Discuss professional societies' recommendations for the prevention and treatment of bone loss after bariatric surgery.

including diabetes, hypertension, dyslipidemia, osteoarthritis, and sleep apnea. Obesity doubles the medical expenditures of adults relative to those of normal weight, and it increases expenditures on inpatient and outpatient care as well as on prescription drugs [2].

## 1.1 Bariatric surgery is an effective treatment for obesity

It can be challenging to attain significant weight loss with lifestyle modifications such as diet and exercise. Even with increasing pharmacologic agents available for weight management, for many people, the magnitude of weight loss needed to achieve health goals exceeds what can be accomplished with medication. Furthermore, if weight loss goals are achieved, weight maintenance can be difficult, in part due to metabolic adaptations and changes in energy expenditure that predispose to weight regain.

In contrast, bariatric surgery is a highly effective treatment for obesity. On average for all bariatric surgical procedures, 33% of weight or 43 kg is lost [3]. Generally, perioperative complications are low, with a 0.3% overall 30-day mortality rate, despite multiple coexisting conditions in people with severe obesity [4]. Long-term weight loss appears to be maintained after bariatric surgery, with a systematic review of studies of more than 10 years' duration documenting procedure-specific mean percentages of excess weight loss (%EWL) of 46%–74% [5]. Interestingly, those who undergo bariatric surgery may be able to escape the eventual metabolic adaptations seen with conventional weight loss. While these mechanisms are not well understood, changes in the gut and brain after bariatric surgery may affect energy homeostasis and behavior

## 1. Introduction

Obesity is a chronic disease of staggering proportions and consequences. Defined as a body mass index (BMI)  $\geq 30$  kg/m<sup>2</sup> (Table 59.1), obesity stems from a complex combination of genetic, metabolic, environmental, behavior, and social factors. The prevalence of obesity among adults in the United States in 2017–20 was estimated to be 42%, with 9% prevalence of severe obesity (BMI  $\geq 40$  kg/m<sup>2</sup>) [1]. Obesity is associated with increased mortality through its linkage to comorbidities

**TABLE 59.1** Body mass index (BMI) classification according to the centers for disease control and prevention.

	BMI (kg/m <sup>2</sup> )
Underweight	<18.5
Normal weight	18.5–24.9
Overweight	25–29.9
Obesity (class 1)	30–34.9
Obesity (class 2)	35–39.9
Severe obesity (class 3)	≥40

in favor of sustained weight loss [6]. Long-term prospective studies have also demonstrated decreased overall mortality rates compared with matched controls [7]. For these reasons, bariatric surgery worldwide has increased more than threefold since the early 2000s, and in 2013, more than 460,000 procedures were performed [8].

In addition to dramatic and sustained weight loss with a mortality benefit, bariatric surgery can significantly improve or resolve obesity-related comorbidities. One metaanalysis demonstrated rates of diabetes resolution in 77%, improvement in hyperlipidemia in 70%, hypertension resolution in 62%, and obstructive sleep apnea resolution in 86% [3]. The improvement and resolution of diabetes is particularly impressive and can occur quickly and before significant weight loss. For example, both insulin sensitivity and insulin secretion have been reported to improve within days after bariatric surgery [9]. These effects are more pronounced after malabsorptive procedures such as Roux-en-Y gastric bypass and biliopancreatic diversion. The mechanisms are not yet understood but may relate to gut changes and altered secretion of neuroendocrine hormones.

## 1.2 Indications for bariatric surgery

The National Institutes of Health (NIH) Consensus Development Panel recommends that bariatric surgery be considered for carefully selected patients with severe obesity as defined by BMI  $\geq 40$  kg/m<sup>2</sup> or  $\geq 35$  kg/m<sup>2</sup> with major obesity-related comorbid conditions [10]. These include conditions such as cardiopulmonary disease (for example, sleep apnea, obesity-related cardiomyopathy) or severe type 2 diabetes mellitus (T2D). There is a newer consensus that bariatric surgery be considered for those with BMI 30–34.9 kg/m<sup>2</sup> and T2D with inadequate glycemic control despite optimal lifestyle and medical therapy [11]. For adolescents, leading professional societies suggest the consideration of bariatric surgery if BMI  $\geq 40$  kg/m<sup>2</sup> (or 140% of the 95th percentile for age and sex) or  $\geq 35$  kg/m<sup>2</sup> (or 120% of the 95th percentile for age and sex) with

concurrent severe comorbid disease [12,13]. The patient should have careful evaluation by a multidisciplinary team with medical, surgical, psychiatric, and nutritional expertise with lifelong medical surveillance.

## 1.3 Bariatric surgery procedures

Historically, bariatric surgery procedures were defined as either restrictive or malabsorptive procedures. Restrictive procedures drastically decrease the stomach size to reduce food intake and promote satiety. Malabsorptive procedures decrease intestinal absorption of nutrients by altering intestinal anatomy and changing how bile and pancreatic fluids interact with ingested nutrients. Combination procedures have both a restrictive and malabsorptive component. Additionally, some procedures have a neurohormonal component that influences hunger and energy balance and contributes to weight loss and other metabolic outcomes. Procedures can be performed open or in a laparoscopic manner, although laparoscopic surgery is generally preferred due to lower rates of complications and shorter hospitalizations. The four bariatric procedures most performed to date are reviewed here (Fig. 59.1). There is increasing interest in surgical procedures such as the single-anastomosis duodenoileal bypass with sleeve gastrectomy and the one-anastomosis gastric bypass (“minigastric bypass”), and in endoscopic procedures, but those are not reviewed here due to limited data about their efficacy and role.

### 1.3.1 Roux-en-Y gastric bypass

Roux-en-Y gastric bypass (RYGB), often called “gastric bypass,” has traditionally been considered the gold standard for bariatric surgery due to its effectiveness in inducing weight loss and associated metabolic benefits. Surgeons have been performing gastric bypass for more than 50 years. It was the most commonly performed bariatric procedure in the United States and worldwide until it was overtaken by the sleeve gastrectomy by approximately 2014 [14,15].

RYGB is considered both a restrictive and a malabsorptive procedure, as well as a neurohormonal one. Gastric restriction occurs with the creation of a <30 mL gastric pouch. The malabsorptive element is achieved by dividing the jejunum and creating an anastomosis between the distal jejunum and the gastric pouch. The resulting biliopancreatic limb, which consists of bypassed stomach, duodenum, and proximal jejunum, is anastomosed distal to the gastrojejunostomy. The length of intestine between the gastrojejunostomy and the biliopancreatic limb anastomosis is called the Roux limb, or alimentary limb. The Roux limb is generally 75–150 cm in length.

**FIGURE 59.1** Bariatric surgery procedures. (A) Biliopancreatic diversion with duodenal switch; (B) Roux-en-Y gastric bypass; (C) adjustable gastric banding; (D) vertical sleeve gastrectomy. *Reprinted with permission from Elsevier.*

### 1.3.2 Sleeve gastrectomy

Sleeve gastrectomy is a more recent bariatric surgical procedure that rapidly gained popularity, representing 0% of bariatric operations worldwide in 2003, then 37% in 2013, then overtaking RYGB as the most popular procedure in the United States, and worldwide in approximately 2014 [14,15].

Sleeve gastrectomy is performed by removing >80% of the stomach and creating a tubular section along the lesser curvature of the stomach. The intestinal tract remains unaltered, and so it has been expected to have fewer nutritional deficiencies than a malabsorptive bariatric procedure. Sleeve gastrectomy is less invasive and less technically challenging than RYGB. Interestingly, its mechanism of action is not simply restriction; it also produces neurohormonal effects that induce weight loss. Weight loss is close to that achieved with RYGB [16,17], although resolution of T2D is less than with RYGB [18]. Similar weight loss benefits and lower surgical complication rates have fueled the increasing popularity of sleeve gastrectomy.

### 1.3.3 Adjustable gastric band

Adjustable gastric banding is performed laparoscopically and commonly referred to as the “lap band.” Its popularity peaked in 2008 and then declined. Gastric banding is a reversible restrictive procedure, in which a band is placed 1–2 cm below the gastroesophageal junction to create a gastric pouch <30 mL. The band can be adjusted by injecting saline into a subcutaneous port that is linked to a balloon within the band. The band can be tightened for further weight loss or loosened if the patient has side effects such as nausea or vomiting. There is less long-term weight loss and less improvement in comorbidities than after RYGB [11], and concerns about procedure-specific complications such as band slip/prolapse, esophageal dilatation, band erosion, and device leak have further diminished its use.

### 1.3.4 Biliopancreatic diversion with duodenal switch

Biliopancreatic diversion (BPD) accounts for only a very small proportion of bariatric operations performed [8]. A combination malabsorptive/restrictive procedures with neurohormonal effects, the biliopancreatic diversion induces very substantial malabsorption, with intestinal anatomy altered so that bile and pancreatic fluids do not meet ingested fluids until the ileum. BPD with duodenal switch (BPD-DS), a modification, is now more frequently performed to minimize dumping syndrome, increase gastric restriction, and decrease ulceration. During a BPD-DS procedure, a sleeve gastrectomy is performed, and the surgeon creates a tubular section along the lesser curvature of the stomach. Then a biliopancreatic limb is created and anastomosed to the distal ileum, approximately 50–100 cm from the ileal cecal valve. For intestinal continuity, the ileum is anastomosed to the duodenum. While BPD-DS is one of the most effective procedures for weight loss, it is a technically challenging operation, and there are higher rates of nutritional complications given the greater degree of malabsorption compared with RYGB.

## 2. Skeletal effects of bariatric surgery

The effects of bariatric surgery on biochemical markers of bone turnover and on bone mass are well documented in prospective cohort studies, as summarized in narrative and systematic reviews and metaanalyses [19–24]. The effects of RYGB have been extensively described [25], and fewer studies have addressed other bariatric procedures. Data on the effects of bariatric surgery on bone microstructure are limited for any procedure. These are summarized here, as well as the growing body of literature about fracture risk after bariatric surgery. Emphasis is placed on human studies, but select findings from rodent models of bariatric surgery are

noted as well. To provide additional context for skeletal changes after bariatric surgery, the skeletal effects of nonsurgical weight loss are summarized.

## 2.1 Bone turnover markers

Biochemical markers of bone turnover increase after bariatric surgery [19,26–28]. This phenomenon has been documented after all of the modern bariatric surgical procedures, although the magnitude of bone resorption marker increase appears to vary by procedure. The increases are smaller after gastric banding than after RYGB [29]. RYGB has been shown to produce similar [30] or larger [31,32] increases in bone turnover markers than sleeve gastrectomy.

After RYGB, increases in the bone resorption marker serum C-terminal telopeptide (CTx) are commonly 200% at 12 months [26,27]. In contrast, changes in biochemical markers of bone formation are more variable, with increases usually smaller in magnitude and occasionally not observed at all [26–28]. In one study of 44 adults with obesity undergoing RYGB, an uncoupling index was calculated, reflecting the relative balance of bone resorption and formation [33]. Six-month increases in bone resorption were more than three times greater than increases in bone formation, and there was a positive correlation between the uncoupling index and changes in vertebral volumetric BMD, such that an uncoupling index more heavily favoring resorption was associated with greater decline in vertebral volumetric BMD. “Uncoupling” of resorption and formation has also been reported in rat models of RYGB [34–36].

Increases in bone turnover markers occur very early and are sustained: Serum CTx was recently shown to have increased at a mere 10 days after RYGB [29]. Serum CTx level is significantly higher than baseline by 1 month after sleeve gastrectomy [30] and by 6 months after gastric banding [37]. After RYGB, marker levels peak at 6–12 months but then remain elevated even when weight loss plateaus [38]. Bone turnover marker levels after RYGB and sleeve gastrectomy remain above baseline at least 5 years postoperatively [39,40].

## 2.2 Bone mass

Most clinical studies of the effects of bariatric surgery on bone mass have used dual-energy X-ray absorptiometry (DXA) to assess bone mineral density (BMD). However, assessment of BMD by DXA may be biased in the setting of marked weight loss due to changes in the composition of the soft tissue surrounding bone [41,42]. Further, spurious increases in spinal BMD by DXA may be detected in the setting of degenerative change. Quantitative computed tomography (QCT) is

an established method for assessing volumetric BMD at the axial skeleton or at the appendicular skeleton, the latter sometimes undertaken by high-resolution peripheral QCT (HR-pQCT). Although obesity and weight loss can also influence QCT assessments [43], QCT avoids the traditional biases of DXA. In addition, unlike DXA, these methods can distinguish cortical from trabecular bone compartments. Effects of bariatric surgery on bone mass assessed by DXA are summarized here, along with the data that exist about the effects of RYGB on bone mass assessed by QCT and HR-pQCT.

### 2.2.1 Roux-en-Y gastric bypass

Since the mid-2000s, numerous longitudinal studies have used DXA to evaluate the effects of RYGB on bone mass and have documented clear decreases in areal BMD [21,22,24,25]. At the proximal femur, the magnitude of the decrease in BMD by DXA is striking, with 12-month declines ranging from 5% to 11% [26,27]; on par with the bone mass, a woman might lose over the first 3–4 years of menopause. At the spine, changes in BMD by DXA are variable but usually constitute declines smaller in magnitude than at the hip. Reported changes in BMD by DXA are also variable at the forearm, often with decreases at the ultradistal and total forearm but not the 1/3 distal radius scan regions [26,27].

Decreases in DXA-assessed BMD have been documented as early as 6 months postoperatively [26–28,30,38,44], and progress with time. Longitudinal studies evaluating BMD beyond 1 year after RYGB have shown progressive BMD decline, even after weight loss plateaus [38,45], or despite mild weight regain [46]. This pattern of continued bone loss despite cessation of weight loss has concerning implications for post-RYGB patients.

Because assessment of BMD by DXA may be biased in the setting of marked weight loss, and because spinal BMD by DXA may be spuriously increased in the setting of degenerative change, it has been important to confirm postoperative decreases in bone mass using QCT. Studies examining axial volumetric BMD by QCT or appendicular volumetric BMD by HR-pQCT after RYGB have substantiated the decreases in areal BMD by DXA [25]. DXA may underestimate BMD decline at the spine [25]. For example, in a prospective study of 21 adults followed for 5 years, areal BMD assessed by DXA declined by a mean 7.8% at the spine, while mean decline in trabecular volumetric BMD assessed by QCT was 15.3% [40]. Five-year BMD decline at the hip was similar in magnitude when assessed by DXA and QCT.

### 2.2.2 Sleeve gastrectomy

Because sleeve gastrectomy is a newer procedure, its effects on bone mass have not been defined well.

Human studies to examine bone mass after sleeve gastrectomy are often limited methodologically by lack of prospective design, very short duration, and small size [26,27]. Most have assessed areal BMD by DXA. Studies using DXA have consistently shown decreases in BMD of 3%–10% at the hip over 12 months [47,48]. Changes in BMD at the spine have been inconclusive [24,47], perhaps because the spine is particularly vulnerable to measurement artifact from degenerative disease and soft tissue artifact. QCT may thus be very helpful, although at this time only a few studies exist to have used QCT to measure volumetric BMD after SG [49–51].

Of the studies published to date that compare areal BMD changes after RYGB versus sleeve gastrectomy, several suggest greater BMD reductions at the total hip after RYGB, although others suggest no difference [24]. Two randomized trials comparing RYGB with sleeve gastrectomy, with BMD reported as a secondary outcome, suggest more deleterious loss of bone mass after RYGB than sleeve [52,53]. Meanwhile, in rat models of sleeve gastrectomy and RYGB, bone volume is significantly lower after RYGB than after sleeve gastrectomy [34].

More data are needed about bone mass after sleeve gastrectomy, including data from larger cohorts, CT-based imaging modalities, and longer-term follow-up. With sleeve gastrectomy and RYGB, the predominant procedures performed now, a better understanding of the relative effects of the two procedures will be important for the fully informed decision-making of patients and clinicians alike.

### 2.2.3 Adjustable gastric band

Fewer data exist about bone mass in the gastric banding patient than in the RYGB patient, presumably because use of the purely restrictive gastric band has declined in recent years as interest in studying skeletal outcomes has increased. The published studies have assessed areal BMD by DXA. In general, it appears that BMD decreases modestly at the proximal femur and is preserved at the spine [26,27]. For example, in one longitudinal study of 37 premenopausal women, femoral neck BMD by DXA decreased from baseline by 2.3% at 12 months and by 5.8% at 24 months, while measured spinal BMD had increased from baseline at 12 months and was not significantly different than baseline at 24 months [37]. In a longitudinal study of 26 men and women, total body bone mineral content by DXA declined from baseline by 2.8% over 24 months, on par with a decline of 2.0% observed in a group that underwent medical weight loss [54]. In a study comparing longitudinal changes in BMD by DXA after gastric banding, sleeve gastrectomy, and RYGB, BMD at the proximal femur decreased in all

three groups but more significantly after RYGB than after gastric banding [55].

### 2.2.4 Biliopancreatic diversion with duodenal switch

Consistent with the observations of defective mineralization, increased bone resorption, and decreased bone formation on histomorphometry in an early study of BPD-DS [56], DXA-assessed BMD has been shown to decrease after BPD-DS [57,58]. One longitudinal study reported decreased BMD at the spine after 1 year [57], while another reported no change in BMD at the spine but decreased BMD at the hip after 10 years [58]. As with gastric banding, the paucity of prospective data about bone mass after BPD or BPD-DS is presumably due to the substantial decline in popularity of the procedures.

## 2.3 Bone microstructure

Cortical and trabecular microstructural properties are important determinants of bone quality and strength [59]. Understanding changes in these properties may elucidate the effects of bariatric surgery on skeletal health. In rodents, RYGB has detrimental effects on trabecular [34–36,60] and cortical [36,60] microarchitecture compared with sham surgery. One of the studies examining trabecular microarchitecture showed that rats undergoing sleeve gastrectomy did not experience the detrimental effects [34].

In humans, iliac crest bone biopsies were performed before and 4 years after BPD in 33 adults, with changes including increased osteoid volume and decreased cortical thickness [58]. HR-pQCT is an advanced imaging modality that quantitatively characterizes trabecular and cortical microstructure at the human radius and tibia [61], serving as a “virtual bone biopsy.” Microstructural parameters assessed by HR-pQCT have been reported in several bariatric surgery studies, with participants undergoing RYGB [38,62] or RYGB, sleeve gastrectomy, and gastric banding [63]. Another study looked adolescents and young adults undergoing sleeve gastrectomy, compared with nonsurgical controls [64]. Findings have included deterioration of both trabecular and cortical architecture, with declines in trabecular number and increases in trabecular heterogeneity and decreases in cortical thickness. By finite element analysis, estimated bone strength has been shown to decrease at the radius and/or tibia. In a cross-sectional study of adults who underwent RYGB or adjustable gastric band at least 10 years prior, compared with nonsurgical controls matched on age, sex, and current BMI, those with a history of RYGB had deficits in cortical and trabecular microarchitecture at the radius and tibia compared with controls [65].

## 2.4 Fracture risk

The question of ultimate importance is whether risk of fracture is higher after bariatric surgery, and the literature addressing this question has expanded rapidly, including retrospective and prospective cohort studies [66–76] and systematic reviews and a metaanalysis [24,77]. Interpretation of studies is complicated by heterogeneity in control group selection, but taken together, the literature shows a higher risk of all fractures after bariatric surgery. Fracture risk is time-dependent, as the increased risk seems to appear 2–3 years after surgery [24,77]. For example, in a French population-based cohort study, there were no significant differences in major osteoporotic fracture risk between gastric bypass patients and nonsurgical patients with obesity until 3 years after surgery, at which time fracture risk progressively increased [74].

The increased fracture risk after bariatric surgery is driven by the procedures that have a malabsorptive component, such as RYGB and BPD-DS [24,77]. In a Canadian retrospective cohort study, bariatric surgery in general was associated with an increased risk for fracture, but in procedure-specific analyses, only BPD-DS clearly associated with a higher risk [70]. A Swedish study specifically examined RYGB and documented higher fracture risk than controls with obesity, regardless of diabetes status [73]. Fracture risk does not appear to be increased after adjustable gastric band, and indeed, investigators conducting a pair of studies in the United States used adjustable gastric bypass patients as the comparison group; fracture after RYGB was documented to be higher [71,72].

Whether fracture risk is increased after sleeve gastrectomy remains unclear because it is a newer procedure. Older studies of fracture risk after bariatric surgery included few or no sleeve gastrectomy procedures, and more recent studies including sleeve gastrectomy have shown no increased fracture risk but after limited follow-up time [74,75]. Longer-term follow-up from larger numbers of people undergoing the procedure is needed.

Studies reporting on anatomic site of fracture have yielded variable results. Higher fracture risk has been reported at the hip, wrist, and other upper extremity sites [71–73].

In summary, there is a clear cause for concern that those who undergo weight loss surgery may be at higher risk for fracture-related morbidity and mortality than their peers.

## 2.5 Comparison with nonsurgical weight loss

When considering the clinical importance of bone loss after bariatric surgery and the potential mechanisms of the bone loss, it is worth considering what is known about the skeletal effects of nonsurgical weight loss.

Bone mass does decline with nonsurgical weight loss, and there is interest in weighing whether this is a concerning finding reflective of excessive skeletal fragility, or whether this is simply an appropriate physiologic adaptation to a new, lower body weight [78].

Most studies of bone health during weight loss have examined older adults. Large epidemiologic studies have shown consistently that weight loss is associated with higher fracture risk in older adults [78], although with such studies, there is the possibility that the results are confounded by illness that caused unintentional weight loss and also negative bone effects. To address that concern, older women and men in two large prospective cohort studies were queried about weight loss intention [79,80]. In the setting of overweight or obesity, even voluntary weight loss was associated with incident bone loss and fracture at the hip in older women [79] and incident hip bone loss in men [80]. A number of RCTs, most of 6–12 months' duration, have examined the effects of weight loss interventions on DXA-assessed BMD in older adults with overweight or obesity [78]. In general, the weight loss groups have experienced decreases in body weight of 9%–10% and decreases in BMD of about 2%, with associated increases in bone turnover marker levels.

In contrast to the RCTs of weight loss in older adults, RCTs in younger adults have shown mixed results [78]. Several trials in younger adults have not found BMD decreases by DXA, despite 7%–10% weight loss [81–83]. In a trial of normal weight and mildly overweight adults 20–50 years old who were randomized to caloric restriction or ad lib control diets, the caloric restriction group experienced an 11.5% weight loss over 12 months that was sustained at 24 months (a 10% decrease from baseline) [84]. BMD declined significantly in the caloric restriction group, with an approximately 2% decline by 2 years, and markers of bone resorption increased.

When bone mass is lost during nonsurgical weight loss, it does not seem to be regained in full when weight is regained [85,86]. This is congruent with the observation that when BMD declines and bone microarchitecture changes during spaceflight and with non-weight-bearing after orthopedic surgery, there does not seem to be full recovery after return to normal weight-bearing [87,88].

## 3. Potential mechanisms of bone loss

There are multiple proposed mechanisms for bone loss after bariatric surgery (Table 59.2). Although the specifics and the relative importance of these pathways are unclear, research into potential mechanisms has yielded interesting insights about the relationship between fat and bone, and the roles of muscle, the gut, and the nervous system.

**TABLE 59.2** Potential mechanisms of bone loss after bariatric surgery.

	Glucagon-like peptide-1
	Glucose-dependent insulinitropic peptide
Bone marrow adipose tissue changes	

### 3.1 Nutritional deficiencies: vitamin D and calcium

Calcium is critical for numerous biological processes, including muscle contraction, neuronal excitability, hormone release, and blood clotting [89]. To facilitate these processes, the body's extracellular calcium concentration is maintained within a narrow range through contributions from the intestine, kidney, and skeleton. Calcium acquisition requires adequate intestinal calcium absorption, and adaptations in renal calcium reabsorption assist with maintenance of homeostasis. The skeleton is a major calcium reservoir, and bone resorption may increase if needed to maintain serum calcium concentration. Calcium homeostasis is regulated primarily by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D [ $1,25(\text{OH})_2\text{D}$ ]: A reduction in serum calcium concentration stimulates release of PTH from the parathyroid glands, and PTH enhances renal calcium reabsorption and bone resorption. PTH also stimulates the conversion of 25-hydroxyvitamin D [ $25(\text{OH})\text{D}$ ] to  $1,25(\text{OH})_2\text{D}$ , which then enhances intestinal calcium absorption. In addition,  $1,25(\text{OH})_2\text{D}$  may have direct effects on bone, by increasing resorption and inhibiting mineralization [90].

In the setting of vitamin D deficiency or calcium deficiency (whether from inadequate intake or from

malabsorption), calcium homeostasis is disrupted. When bone resorption increases to maintain the extracellular calcium concentration, it does so at the expense of bone mass and quality, and skeletal health may suffer.

#### 3.1.1 Vitamin D

There is a high prevalence of vitamin D insufficiency or deficiency in the setting of obesity, so those who undergo bariatric surgery may have suboptimal vitamin D status even before their operations. An inverse relationship between BMI and  $25(\text{OH})\text{D}$  level is very well documented [91–93] (See Chapter 75, “Vitamin D, Obesity, and the Metabolic Syndrome,” Hypponen and Boucher.). This has been attributed to sequestration or volumetric dilution of the fat-soluble vitamin in adipose tissue [94,95], and to low sun exposure [96]. Further, obesity has been associated with the decreased expression of enzymes involved in 25-hydroxylation and  $1\alpha$ -hydroxylation in adipose tissue [97], raising the possibility that vitamin D metabolism is impaired in obesity. In studies of individuals with severe obesity preparing for bariatric surgery, mean preoperative  $25(\text{OH})\text{D}$  levels are consistently below 30 ng/mL and often below 20 ng/mL [98].

After RYGB and BPD-DS, problems with vitamin D absorption and intake may threaten vitamin D status. The intestinal absorption of fat-soluble micronutrients, including vitamin D, depends on timely interactions with bile and pancreatic enzymes. Because food and supplements ingested after RYGB or BPD-DS do not mix with bile and pancreatic enzymes until after the biliopancreatic limb joins the alimentary limb to form the common channel, malabsorption of vitamin D may occur postoperatively. In addition, for each of these procedures, because overall food consumption is so dramatically decreased by the restrictive components of the operations, smaller amounts of vitamin D-containing food may be consumed [99].

Indeed, studies have documented a very high prevalence of vitamin D insufficiency or deficiency after RYGB or BPPDS [98,99], although reported prevalence varies substantially due to heterogeneity in postoperative supplementation. After sleeve gastrectomy or adjustable gastric banding, the intestinal, biliary, and pancreatic anatomy remains intact, but postoperative deficiencies nevertheless sometimes occur [98,100–102]. This is likely due to preoperative suboptimal vitamin D status, and further, these procedures restrict postoperative dietary intake, including intake of vitamin D-containing foods. Response to supplementation after bariatric surgery is highly variable [98,99,103], with some individuals achieving  $25(\text{OH})\text{D}$  levels above 30 ng/mL on just 400 IU daily and others requiring 50,000 IU daily or more. Overall, a review of randomized controlled trials

concluded that doses of at least 2000 IU daily are needed to reach 30 ng/mL [104]. Another systematic review and metaanalysis of randomized clinical trials identified that dosages of 2850 IU daily are needed to improve vitamin D status [105]. As discussed in later sections of this chapter, professional organizations recommend preoperative repletion of low 25(OH)D levels, routine postoperative vitamin D supplementation, and monitoring of 25(OH)D levels with the adjustment of supplement dose as necessary [106–109].

### 3.1.2 Calcium

Intestinal calcium transport occurs through both an active, transcellular, saturable pathway and also a passive, paracellular, nonsaturable pathway (See [Chapter 18](#), “Regulation of Intestinal Calcium and Phosphate Absorption,” Fleet and Christakos.). The active, transcellular pathway predominates when calcium intake is low, while passive, paracellular transport increases in importance when calcium intake is high. Active, transcellular calcium transport is primarily regulated by 1,25(OH)<sub>2</sub>D; it is increased in the setting of habitually low calcium intake due to increased PTH secretion and activation of 1,25(OH)<sub>2</sub>D, provided that there is sufficient substrate 25(OH)D [110]. In passive calcium transport, calcium is absorbed in a diffusional manner across tight junctions and intercellular spaces [111]. This paracellular process is nonsaturable and directly related to the concentration of calcium in the intestinal lumen, thereby increasing and achieving particular importance in the setting of high calcium intake. While it was originally thought that paracellular transport was independent of vitamin D, more recent research has revealed regulation by 1,25(OH)<sub>2</sub>D [112]. In particular, 1,25(OH)<sub>2</sub>D appears to induce specific claudin proteins at the tight junctions between cells [113,114].

Active, transcellular transport is prevalent in the proximal small intestine (duodenum and jejunum), was traditionally thought to be absent in the ileum, and occurs to a small extent in the colon, while paracellular transport occurs throughout the length of the intestine. There is evidence, however, that active, transcellular transport occurs in the ileum and that active transport may have greater importance than once thought in the colon [112,115–117]. In transgenic mice with *Vdr* expression exclusively in the ileum, cecum, and colon (and otherwise *Vdr*-knockouts), even just the distal intestinal *Vdr* expression prevented the disrupted calcium metabolism and skeletal phenotype of the *Vdr*-null state [117]. To better understand the mechanisms of intestinal calcium absorption in different segments of the intestine, additional research is needed.

Additional regulators of transcellular calcium transport include estrogen [118], growth hormone [119], and glucocorticoids [120], as well as dietary intake of fat

and fiber [121–123]. In addition, intestinal calcium absorption is impaired in the setting of achlorhydria (decreased gastric acidification) [124].

After RYGB and BPD-DS, one could predict that calcium absorption could be either impaired or normal, based on the normal physiology of intestinal calcium transport and on the altered anatomy after those procedures. On the one hand, calcium absorption could be substantially impaired, due to vitamin D insufficiency or deficiency, or due to the fact that the bypassed duodenum and jejunum, which are usually dominant sites of active, transcellular calcium transport, no longer come into contact with food or supplements. (After RYGB, the proximal jejunum is bypassed; after BPD-DS, the entire jejunum is bypassed). Further, achlorhydria from the operation itself and from the common use of postoperative proton pump inhibitors for marginal ulcer prevention could worsen calcium absorption [125,126]. On the other hand, one could predict that sufficient calcium absorption could be achieved postoperatively if vitamin D status and calcium intake are robust, in light of the evidence for meaningful active, 1,25(OH)<sub>2</sub>D-mediated calcium transport in the distal intestine [116,117], and the passive absorption that occurs throughout the gut.

Intestinal fractional calcium absorption (FCA) has been assessed before and after RYGB using dual stable isotopes [127], with one stable calcium isotope administered orally to label dietary calcium and another intravenously to measure calcium removal from the blood. All studies have documented a substantial decline in fractional calcium absorption, although the extent of the decline has ranged from moderate to severe [44,128,129]. One group of researchers measured FCA preoperatively and 6 months postoperatively in 21 women who lost a mean 39 kg during the study period [128]. Mean  $\pm$  standard deviation FCA decreased from 36%  $\pm$  8%–24%  $\pm$  9%. Another group measured FCA in premenopausal women ( $n = 20$  to 23 at each time point) and found that FCA decreased from a mean 41.5%  $\pm$  2.8% preoperatively to 27.9%  $\pm$  3.8% and 18.5%  $\pm$  2.2% at 12- and 24-month time points, respectively [129]. Riedt and colleagues used a larger (200 mg) calcium test load, while Carrasco and colleagues' low-calcium (17.6 mg) test load to measure only active calcium absorption. In both studies, over half the participants had 25(OH)D levels less than 25 ng/mL, and mean postoperative calcium intake was less than 1000 mg at some or all time points. Thus, while these two studies provide very important documentation of FCA decline, it cannot be concluded whether robust vitamin D status and consistent, ample calcium intake could mitigate postoperative declines.

To address that gap in knowledge, in 33 women and men with obesity undergoing RYGB, FCA was

determined in the setting of a target 25(OH)D level of at least 30 ng/mL and calcium intake of 1200 mg daily [44]. Upon enrollment, low 25(OH)D levels were repleted to the target range, and total daily calcium intake was brought to goal through personalized dosing of a calcium citrate supplement, based on dietary intake. Postoperatively, 25(OH)D levels and dietary calcium intake were monitored, and the personalized supplement doses were adjusted as needed to maintain target levels and intakes. Achieved 25(OH)D levels were a median (interquartile range) 41 [33–49] ng/mL preoperatively and 37 [29–40] ng/mL postoperatively. A 10 mg dose of oral calcium-44 was administered in the middle of a standardized test breakfast with 300 mg calcium, and a 3 mg dose of calcium-43 infused intravenously 1 h later, with blood drawn 24 h later for isotope enrichment by mass spectrometry and FCA determination.

Preoperatively, mean FCA was  $33\% \pm 14\%$ , within the range expected for a group composed largely of middle-aged women [121,130]. Postoperatively, FCA decreased dramatically to a mean of  $7\% \pm 4\%$  (Fig. 59.2). Given that total daily calcium intake (from diet and supplements) was 1200 mg at both time points, total daily absorbed calcium fell from  $392 \pm 168$  mg to  $82 \pm 45$  mg. Corroborating and presumably responding to the FCA decline, PTH increased modestly from a median level of 41 [32–53] pg/mL preoperatively to 48 [39–59] pg/mL postoperatively ( $P = .02$ ), and 1,25(OH)<sub>2</sub>D increased from 37 [34–46] pg/mL to 51 [41–63] pg/mL ( $P < .001$ ). Median 24-h urinary calcium decreased ( $P < .001$ ) [44]. Participants with greater percentage weight loss had greater declines in FCA, a finding potentially consistent with the published observation that nonsurgical weight loss results in a decline in FCA compared with weight maintenance [131,132].

**FIGURE 59.2** Fractional calcium absorption before and 6 months after Roux-en-Y gastric bypass surgery, in the setting of standardized calcium intake and robust vitamin D status. Values are mean  $\pm$  SD. Reprinted with permission from Schafer et al. [44].

Alternatively, this finding might be explained by variability in surgical approach, such that those with more intestine bypassed might have experienced more weight loss and also a larger impact on calcium absorption. It is unclear why the observed FCA decrease was more severe than in the studies by Riedt and colleagues and Carrasco and colleagues, but it is clear that maintaining robust vitamin D status and calcium intake does not mitigate the FCA decline after RYGB. Our findings more closely resemble results of early studies of calcium absorption after the jejunoileal bypass, an older bariatric procedure [133,134].

In this cohort of 33 adults undergoing RYGB, those with greater percentage declines in FCA or lower postoperative FCA had greater increases in the bone resorption marker CTx [44]. BMD declined substantially, by a mean 4.6% in areal BMD at the femoral neck and 6.5% in volumetric BMD at the spine. There was not a statistically significant correlation between the extent of the FCA and BMD changes, potentially reflecting the influence of other important factors on BMD, such as mechanical unloading of the skeleton and changes in adipokines and gut-derived hormones, and it does not preclude a contribution of the FCA decline to the BMD decline. In fact, greater increases in PTH—which increased only modestly overall—correlated with greater decreases in BMD at the femoral neck (Fig. 59.2).

A conceptual model for the changes in calcium homeostasis after RYGB integrates these findings (Fig. 59.3). Intestinal calcium absorption is impaired after RYGB, which results in an increase in PTH secretion, which increases bone resorption as a measure to maintain adequate serum calcium concentration. It is possible that 1,25(OH)<sub>2</sub>D has direct skeletal effects as well. Meanwhile, there is concurrent non-PTH-mediated stimulation of bone resorption and loss of bone mass, such that the dramatic increases in bone turnover markers and declines in BMD reflect a multifactorial process. (Such non-PTH-mediated processes are discussed in the next sections of this chapter.) By mobilizing calcium from the skeleton, non-PTH-mediated processes such as mechanical unloading or changes in adipokines or gut-derived hormones may dampen the need for particularly high levels of PTH, providing an explanation for the modest PTH change—or no change—detected in these studies.

Sleeve gastrectomy also results in decreased FCA [129,135]. In one study, FCA was determined using a dual stable isotope approach in premenopausal women ( $n = 13$  to 19 at each time point). FCA decreased from a mean  $36.5\% \pm 2.0\%$  preoperatively to  $21.0\% \pm 2.3\%$  and  $18.8\% \pm 3.4\%$  at 12 and 24 months after surgery, respectively [129]. A study of women and men yielded similar results before and 6 months after surgery: FCA decreased from  $31.4\% \pm 15.4\%$  preoperatively to  $16.1 \pm 12.3\%$  postoperatively, while median

FIGURE 59.3 Effect of Roux-en-Y gastric bypass on calcium homeostasis. Adapted with permission from Elsevier.

(interquartile range) 25(OH)D levels were 39 [32–46] ng/mL and 36 [30–46] ng/mL, respectively [135]. Concurrently, median 1,25(OH)<sub>2</sub>D level increased, without significant changes in PTH level. Individuals with lower postoperative FCA had greater aBMD loss at the total hip.

Why does FCA decline when the intestine remains intact after the sleeve gastrectomy procedure? It is possible that sleeve gastrectomy induces changes in hormones and nutritional parameters implicated in intestinal calcium transport [118,119,121–123]. Indeed, in the 6-month study, participants with greater postoperative increases in IGF-1 levels had higher postoperative FCA [135]. Postoperative use of prophylactic proton pump inhibitors (PPIs) is very common, but a sensitivity analysis was performed excluding PPI users, and the FCA results were similar. Sleeve gastrectomy does diminish gastric acid independent of PPI use, and that may still be a contributor. Further, even nonsurgical weight loss is associated with a decline in calcium absorption capacity compared with weight maintenance [131,132]. Regardless of the reason for the FCA decline, the decline may contribute to loss of bone mass and microstructural integrity after sleeve gastrectomy.

### 3.2 Mechanical unloading

The skeleton adapts to mechanical strain and maintains bone mass and architecture adequate to withstand the loads of everyday activity [136]. Through adaptive remodeling, new bone is added in response to increased loading, and bone is removed in response to decreased loading or disuse. The osteocyte is the major cell type responsible for sensing and translating mechanical strain, as well as orchestrating remodeling [137]. This orchestration is complex and includes the secretion of sclerostin, a load-responsive inhibitor of bone formation [138]. In rodents, skeletal unloading causes loss of bone mass, with

transient increases in bone resorption followed by sustained decreases in bone formation, and with loss of bone mass first at weight-bearing bones [139]. In humans, bed rest [140], space flight [141], and restricted weight-bearing after orthopedic surgery [87] are each associated with declines in bone mass and content. The mechanical unloading has been shown to impact both cortical and trabecular bone mass and microstructure [87,141], with impressive, detrimental increases in the porosity of cortical bone and associated decreases in bone strength.

The dramatic weight loss after bariatric surgery results in the relative unloading of the skeleton. In many studies of bariatric surgery and skeletal health, those with greater weight loss have had greater decreases in BMD [26,27,45]. The hip typically carries more load than the spine, and many studies assessing axial BMD by DXA have shown greater BMD decreases at the hip than spine [27]. Detrimental microstructural changes assessed by HR-pQCT may be worse at the weight-bearing tibia than the non-weight-bearing radius [63]. One recent study showed that sclerostin levels increase after bariatric surgery, and increases in sclerostin correlated with increases in bone turnover markers and decreases in BMD [30].

However, bariatric surgery's effects are complex, and these findings might not simply reflect mechanical unloading. The correlation between extent of weight loss and extent of BMD decline might exist because those with greater weight loss have more severe changes in nutritional status, or more dramatic changes in adipokines, sex hormones, or gut-derived hormones. The correlation could also be the result of measurement bias in the setting of marked weight loss and body composition change. Limitations of available skeletal imaging modalities also require that caution be used when comparing BMD changes at the hip and spine during weight loss [142]. In fact, increases in bone turnover persist [38], and decreases in BMD progress [38,45,46] even after weight loss plateaus. Moreover, a study showed that adults with a history of RYGB at least 10 years prior

had lower BMD and deficits in trabecular and cortical microstructure compared with BMI-matched nonsurgical controls, while adults with a history of adjustable gastric banding were not different than controls [65]. For all these reasons, it seems unlikely that the skeletal changes after bariatric surgery are exclusively the response to mechanical unloading and the appropriate adaptation to a smaller body frame.

### 3.3 Loss of muscle mass

Muscle has long been recognized as the primary source of anabolic mechanical stimuli for bone tissue [143,144]. Skeletal muscle contractions power human body movements, and the long-term loading forces exerted by muscles stimulate increases in bone mass. Age-related losses of muscle mass, strength, and function (termed “sarcopenia”) [145,146] are associated with loss of bone mass, and changes in muscle and bone mass induced by exercise or disuse are usually closely coupled as well. In addition to direct effects on bone, loss of muscle mass, strength, and function can increase fracture risk by increasing fall risk. Contributors to muscle strength and function include diet and hormones such as insulin-like growth factor 1, growth hormone, testosterone, and 1,25(OH)<sub>2</sub>D. Fat infiltration of muscle (myosteatosis) is also a factor [147]. Lipid within and surrounding muscle cells is associated with decreased strength and increased mobility loss in older adults [148,149], as well as with increased risk of incident fracture [150,151].

Bariatric surgery causes loss of muscle mass [152–158], although to a relatively lesser extent than the concomitant loss of fat mass [152,158,159]. Lean mass accounts for an average of 21%–28% of total weight loss in the first postoperative year, with the majority of the muscle mass loss in the first 6 months [152,160]. After the first 6 months, the extent of lean mass lost is highly variable, with some patients experiencing continued loss, and others with muscle mass maintenance or gain [160]. In conjunction with the overall loss of lean mass, absolute muscle strength declines [154,156,158]. However, when muscle strength is considered in relation to body weight (i.e., maximal force or torque per kg body weight), this measure of muscle quality increases [153,156,158]. In muscle biopsy studies, muscle lipid content (intramyocellular lipid) decreases after bariatric surgery [161,162]. Of studies that have examined physical performance before and after bariatric surgery (e.g., with 6-min walk distance), most conclude that physical function improves [153,157,158,163–165].

In the context of dramatic changes in body composition following bariatric surgery, absolute or relative declines in muscle mass and quality might exacerbate decreases in BMD and bone strength, while

improvements in muscle parameters might mitigate the negative skeletal effects of the procedure. Indeed, a correlation between decline in lean mass and decline in BMD has been reported [46,166].

### 3.4 Adipokines

Adipose tissue is more than an energy storage site; it is an active endocrine organ with systemic effects including on bone. There is also cross-talk between adipose tissue and bone. For example, adipocytes secrete several factors known to influence bone physiology such as leptin, adiponectin, tumor necrosis factor- $\alpha$ , and interleukin-6. Meanwhile, bone-derived factors such as osteocalcin and osteoprotegerin directly affect adipocytes, body weight, and glucose homeostasis.

#### 3.4.1 Leptin

Leptin is a hormone secreted by adipocytes that plays an important role in food intake, energy expenditure, reproduction, glucose metabolism, and fat metabolism. Circulation of leptin is proportional to fat stores, so people with obesity have increased plasma leptin levels [167]. Leptin receptors are expressed at high levels in hypothalamic nuclei such as the ventromedial and arcuate nuclei, where leptin serves as a signal of nutritional status and energy storage.

Bone is responsive to energy dynamics and is also affected by leptin. In vitro, leptin appears to have an anabolic effect and has been shown to increase osteoblast proliferation and inhibit osteoclastogenesis, without effect on bone resorption in mature osteoclasts [168,169]. In contrast, in vivo studies of leptin on bone physiology demonstrate a more complex relationship. Leptin-deficient *ob/ob* mice have a high bone mass phenotype, despite hypogonadism and hypercortisolism associated with leptin deficiency [170]. In particular, trabecular volume is increased, whereas cortical bone does not appear to be affected. Leptin is thought primarily to affect bone physiology through neural mechanisms. In mouse genetic studies, deletion of the leptin receptor in neurons results in the high bone mass phenotype seen in leptin-deficient mice, whereas the same deletion in osteoblasts does not influence bone remodeling [171]. Intracerebrovascular infusion of leptin reverses the high bone mass phenotype in *ob/ob* mice and causes trabecular bone loss [170]. Within the central nervous system, sympathetic nervous system signaling appears necessary for the effects of leptin on bone; in mice that have had genetic or pharmacologic ablation of adrenergic signaling, intracerebrovascular infusion of leptin fails to reverse the high bone mass phenotype [172]. Further, there are beta-adrenergic receptors on osteoblasts that regulate

proliferation, and beta-adrenergic agonists decrease bone mass, while beta-adrenergic antagonists increase it [172]. Ultimately, the pathophysiology is not completely understood, and effects of leptin may be different peripherally versus centrally, particularly on cortical bone. For example, *ob/ob* mice that received subcutaneous leptin for 2 weeks had increased tibial bone formation and whole-body bone mineral content [173].

In humans, obesity is associated with higher plasma leptin levels, consistent with leptin resistance, and these levels fall with weight loss [167]. In bariatric surgery, there is a decline in plasma leptin that is associated with the degree of postoperative weight loss [174]. Some studies have identified an association between decrease in plasma leptin and increase in bone turnover marker level or decrease in BMD [45,175], although this association may be confounded by the extent of weight lost.

### 3.4.2 Adiponectin

Adiponectin is a factor secreted by adipocytes and involved in energy homeostasis, glucose, and lipid metabolism as well as inflammation [176]. It is relatively abundant in plasma [177]. Although adiponectin is secreted from adipocytes, levels are paradoxically lower in obesity [177]. Low levels of adiponectin in humans are also associated with insulin resistance and cardiovascular disease.

Most human studies report a negative association between adiponectin and BMD in healthy adults, independent of sex and menopausal status [178]. A relationship between higher adiponectin and lower BMD, independent of fat mass, has also been observed in adolescent girls with anorexia nervosa [179] and in people with diabetes mellitus [180].

In contrast to human studies, findings from in vitro studies are inconsistent, and the mechanism of adiponectin on bone is not completely understood. Both adiponectin and its receptors are expressed from osteoblasts and osteoclasts [181]. Contrary to the negative association with BMD in clinical studies, adiponectin stimulates osteoblasts and inhibits osteoclasts in vitro [182,183]. Adiponectin has also been shown to induce receptor activator of nuclear factor kappa-B ligand (RANKL) and inhibit osteoprotegerin expression in osteoblasts, which contribute to osteoclast formation in a coculture of osteoblasts and peripheral blood monocytes systems [184]. Adiponectin could also affect bone indirectly via its effects on insulin sensitivity or other mechanisms.

Adiponectin levels increase after bariatric surgery [174], consistent with postoperative fat loss. Most studies examining adiponectin level in relation to bone changes after bariatric surgery have not generally suggested an association [45,175,185]. One study that did report a significant association demonstrated that in 42

women undergoing RYGB, adiponectin level at 12 months correlated with total BMD decrease ( $r = 0.35$ ,  $P < .05$ ) after adjustment for baseline weight, baseline body fat, baseline BMD, weight loss, and total and regional body fat loss [159].

## 3.5 Sex steroids

Gonadal steroids are important for skeletal growth and maintenance. In particular, estrogen acts through a variety of mechanisms to suppress bone resorption and increase bone formation. Estrogen plays a significant role in skeletal health in both women and men. In men, testosterone has modest antiresorptive effects and also contributes to bone formation.

Adipose tissue is the main source of estrogen in men and postmenopausal women. In obesity, the excess adipose tissue in men and increased aromatization to estrogen can lead to hypogonadotropic hypoandrogenism. Even though sex hormone-binding globulin (SHBG) is decreased in obesity, free levels of testosterone are low as well.

Bariatric surgery results in dramatic loss of fat mass, which subsequently affects sex hormone levels. These changes have been best described in men, in whom weight loss has been shown to be associated with an increase in total testosterone, SHBG, and calculated free testosterone [186]. Bariatric surgery is more effective at increasing testosterone than low-calorie diet; in a meta-analysis, total testosterone increased on average by 8.73 nmol/L in men undergoing bariatric surgery, compared with an increase of 2.87 nmol/L in men on a low calorie diet [186]. In both groups, those who lost more weight had a further increase in testosterone and gonadotropins and decrease in estradiol. There have been fewer published analyses of sex hormone changes after bariatric surgery in women. One study of 14 premenopausal women and 2 men with obesity showed a decrease in estradiol levels from baseline to 12 months after vertical banded gastroplasty [187]. Although this has not been demonstrated, one might hypothesize that decline in estrogen after bariatric surgery might contribute to bone resorption in men and women, whereas in men, the increase in testosterone may counter that by contributing to bone formation and mitigating bone loss.

## 3.6 Gut-derived hormones

Surgical manipulation of the gastrointestinal tract changes gut physiology, which is thought to play a significant role in the metabolic effects of bariatric surgery. This is postulated because after the gut is surgically altered, the metabolic effects of bariatric surgery are

seen relatively quickly, and before significant weight loss occurs [9]. In addition, feeding is known to decrease bone resorption markers in healthy people, and this phenomenon is preserved and even amplified in those who have bariatric surgery [29,188]. The mechanism for how bariatric surgery changes these gut hormones is not completely understood. Surgically altered nutrient transit is likely an important mechanism; for example, in malabsorptive surgeries, there is increased nutrient delivery to the distal small intestine where there are cells that secrete gut hormones such as peptide YY and glucagon-like peptide-1 (GLP-1). Bariatric surgery in general could also result in enteroplasticity, or multiple gut adaptations driven by the modified environment of the surgically altered gastrointestinal tract, which results in alterations in enteroendocrine cells, the nervous system, gut morphology, and nutrient signaling [189]. Regardless of the mechanism, these gut hormones play significant roles in appetite regulation, energy balance, and glucose homeostasis, and there is increasing evidence of their effects on skeletal physiology.

### 3.6.1 Peptide YY

Peptide YY (PYY) is a member of the neuropeptide Y family and increases in response to food ingestion to promote satiety [190] and to regulate energy homeostasis [191]. Along with other gut hormones such as GLP-1, PYY is produced by L cells in the distal ileum and colon. PYY is a 36-amino-acid peptide that is cleaved by dipeptidyl peptidase IV to form PYY(3–36). PYY(1–36) has high affinity to all four Y-receptor subtypes, whereas PYY(3–36) is a specific Y2 agonist.

Given its role in appetite and energy homeostasis, it is not surprising that PYY levels differ based on body habitus. Those with anorexia nervosa have elevated fasting PYY levels [192], and those with obesity have lower fasting and prandial PYY levels [193]. After bariatric surgery, PYY levels increase [194,195], which may be due to surgical alterations of the gut rather than weight loss. In a study of adults with obesity treated with either RYGB, sleeve gastrectomy, or medical therapy, weight loss at 2 months was similar between groups, but the bariatric surgery groups had an increase in PYY area under the curve (AUC) in response to a meal, while the medical weight loss group had no significant change in PYY AUC [194].

PYY may play a role in skeletal physiology and contribute to bone loss in bariatric surgery. The skeletal effects of PYY may occur via Y receptors: Y2 receptors in the hypothalamus activate the sympathetic nervous system, and peripheral Y1 receptors on osteoblasts inhibit differentiation [196]. Although studies of PYY knockout mice have shown inconsistent results [197,198], human studies suggest a negative correlation between PYY and BMD [199,200]. In the context of bariatric surgery,

in study of RYGB in 44 adults with obesity, 6-month changes in serum PYY correlated with changes in vertebral volumetric BMD changes by QCT and also with the bone formation marker P1NP [33]. In other words, postoperative PYY increases were associated with attenuated increases in P1NP and greater declines in spine volumetric BMD. Consistent with these findings, in a study of adults with obesity and with type 2 diabetes mellitus who had either RYGB or gastric banding, in the RYGB group, there was a positive correlation between changes in fasting PYY and CTx [29]. At 10 days and at 1 year after RYGB, those with a greater increase in PYY had a greater increase in CTx, which suggests that increases in PYY after bariatric surgery could contribute to bone loss following this otherwise beneficial procedure. However, in contrast to these two studies, in a randomized trial of RYGB, SG, or greater curvature plication, there was no relationship between fasting PYY and 1-year BMD change [52].

### 3.6.2 Ghrelin

Ghrelin is an appetite-stimulating hormone produced in the gastric fundus that increases during fasting, decreases after eating, and also reduces energy expenditure. Posttranslationally, ghrelin is acylated with n-octanoic acid or n-decanoic acid, which results in the active acylated form of ghrelin, although the des-acyl form of ghrelin may have biologic activity as well [201]. In humans, ghrelin is increased in anorexia and decreased in obesity [202], which may reflect a compensatory response of ghrelin to these pathologic states. In anorexia, there is reduced feeding; therefore, the observed increase in ghrelin may represent a decreased sensitivity to ghrelin. Conversely, with obesity and the overabundance of feeding, the decreased ghrelin may represent a compensatory adaptation aimed at reducing hunger stimulus.

In humans, the literature describing ghrelin changes after bariatric surgery is heterogeneous, with studies reporting decreases, increases, or no change in circulating levels [203]. Some heterogeneity may be due to measurement, as measured ghrelin level can vary depending on the assay, collection parameters, and whether the total or acylated form is measured. There also appears, however, to be differential effects of various bariatric surgical procedures. The amount of gastric fundus that remains may significantly affect changes in ghrelin levels. In studies of sleeve gastrectomy, where the gastric fundus is resected, total fasting levels of ghrelin have been reported to decrease [204]. In a study of diet-induced weight loss and gastric bypass, diet-induced weight loss of 17% of initial body weight was associated with a 24% increase in the AUC during a 24-h ghrelin profile—consistent with an increase in appetite. In contrast, despite a 36% weight

loss after gastric bypass, the AUC for the ghrelin profile was 77% lower than in normal weight controls and 72% lower in matched controls with obesity. This reflects the appetite decrease that many report after bariatric surgery. After RYGB, there was also a lack of normal meal-related fluctuations and diurnal rhythm of ghrelin levels. This suggests that ghrelin changes after bariatric surgery are unique to the procedure and may contribute to weight-reducing and metabolic effects of surgery.

Ghrelin binds to the growth hormone secretagogue receptor (GHS-R) and therefore may promote bone formation through its effects on growth hormone and insulin-like growth factor-1. There may be a direct effect as well, since osteoblasts secrete both ghrelin and GHS-R, and ghrelin stimulates osteoblastogenesis in vitro [205]. The bone formation effects of ghrelin are also seen in animal models. For example, ghrelin administration to normal and growth hormone-deficient mice results in increased BMD [205]. However, ghrelin knockout mice have the same BMD as controls [206]; therefore, compensatory mechanisms may counteract the effects of ghrelin deficiency. Human studies of ghrelin and BMD have been inconclusive. While there has been a positive association between ghrelin secretion and BMD in healthy adolescent girls [207], other studies have not shown this relationship [178]. Similarly, there is not a consensus in regard to the relationship of ghrelin and bone changes after gastric bypass in the few published studies. One prospective study of women who had either RYGB or sleeve gastrectomy found that 1 year after surgery, decreases in BMD were more dramatic among patients who had greater reductions in ghrelin concentrations [185], but most studies do not report a relationship between a change in fasting ghrelin and skeletal outcomes [33,52,208].

### 3.6.3 Glucagon-like Peptide-1

Glucagon-like peptide-1 (GLP-1) is secreted in the distal ileum and colon and plays an important role in glucose and energy homeostasis. Along with gastric inhibitory peptide (GIP), GLP-1 is an incretin, which is a hormone that is responsible for the phenomenon of enhanced insulin secretion with oral glucose compared with an isoglycemic intravenous glucose load. In addition to stimulating insulin secretion, GLP-1 also slows gastric emptying, attenuates glucagon secretion, and promotes satiety. The United States Food and Drug Administration (FDA) has approved GLP-1 agonists for diabetes treatment as well as weight loss in obesity. After bariatric surgery, most studies show that there is an increase in GLP-1, especially in response to meals. These changes have been observed as early as 1 week after surgery [9] and are influenced by the type of bariatric surgery performed. There is an increase in GLP-1 after procedures with intestinal rearrangement compared

with gastric banding procedures [209], which may be related to an increase in nutrient delivery to the distal ileum where GLP-1 is secreted. However, sleeve gastrectomy also causes an enhanced GLP-1 response to meals [210], which may be due to increased gastric emptying rather than altered anatomical nutritional transit.

GLP-1 appears to have an anabolic effect on bone. GLP-1 may directly influence osteoblastic cells [211] and has been shown to have an insulin-independent anabolic effect in mice after 3 days of a continuous GLP-1 infusion [212]. Similarly, GLP-1 receptor knockout mice have cortical osteopenia, bone fragility, and increased osteoclastic numbers and bone resorption [213]. There have been few studies of bone health in humans with exogenous GLP-1 administration with conflicting results. In one study, participants with type 2 diabetes mellitus on metformin were randomized to either exenatide or insulin glargine for 44 weeks, and after 6% weight loss, there was no difference in BMD [214]. In contrast, in another study, women with obesity who sustained diet-induced 12% weight loss were randomized to liraglutide for 52 weeks, and there was a loss in bone mineral content in the control group, whereas the group that received liraglutide maintained their bone mineral content [215]. In the context of bariatric surgery, the few published studies do not report a relationship between GLP-1 and skeletal outcomes. A study that examined bone turnover markers after RYGB or gastric banding did not find an association between bone turnover changes and fasting or postprandial GLP-1 [29]. Similarly, a randomized control trial of RYGB, SG, or greater curvature plication did not find a relationship between fasting or postprandial GLP-1 with 1-year BMD loss in regression analyses [52].

### 3.6.4 Glucose-dependent insulintropic polypeptide

Glucose-dependent insulintropic polypeptide, also known as gastric inhibitory peptide (GIP), is an incretin that is secreted in the proximal small intestine in the presence of nutrients in the gut. GIP was first named gastric inhibitory peptide because it was thought to decrease gastric acid secretion; however, later studies demonstrated its main effect is stimulating insulin secretion in response to a meal. GIP is also involved in lipid metabolism and is thought to promote fat deposition. Fasting and prandial GIP levels are elevated in obesity and diabetes compared with matched controls [216]. After bariatric surgery, GIP changes appear dependent on the type of surgery performed. In general, the GIP response to a meal is attenuated after malabsorptive surgeries such as RYGB and BPD-DS [217], while postoperative changes in GIP levels are generally observed after restrictive procedures with intact small bowel anatomy, such as gastric banding.

In addition to effects on glucose and lipid metabolism, GIP appears to have an anabolic effect on bone. GIP receptors are located on both osteoblasts and osteoclasts. GIP *in vitro* has an antiapoptotic effect on osteoblastic cells, and it inhibits resorptive activity of mature osteoclasts [218,219]. *In vivo* studies support the concept of GIP as a gut hormone that is anabolic to bone. GIP receptor knockout mice have decreased bone size, lower bone mass, abnormal bone microarchitecture, and impaired biomechanical properties [220]. Similarly, a transgenic mouse model overexpressing GIP demonstrated an increase in bone formation markers, decrease in resorption markers, and increase in bone mass [221]. One GIP receptor knockout mouse model demonstrated an increase in plasma calcium concentrations after meal ingestion, suggesting that GIP may play a role in calcium homeostasis [218].

There have been few studies of GIP and bone in humans. One study found that exogenous administration of GIP did not change serum CTx levels [222]. In contrast, a cohort study found an association between a GIP receptor polymorphism and bone loss. In the Danish Osteoporosis Prevention study, women with a functional GIP receptor polymorphism Glu354Gln (rs1800437) had significantly lower BMD at the femoral neck and total hip, with an increased risk of nonvertebral fractures [223]. There are fewer studies of GIP and bone in the bariatric surgery population. In a study of people with obesity and diabetes who had either RYGB or gastric banding, there was no change in fasting or prandial GIP and no association with bone turnover markers [29].

### 3.7 Bone marrow adipose tissue

Bone marrow fat appears to serve a metabolic role distinct from the role of subcutaneous or visceral fat. Generally, the location of the fat depot in the body affects the function of that fat. For example, excess visceral fat is associated with a greater risk of diabetes, cardiovascular disease, and mortality, in part because visceral fat produces proinflammatory cytokines. Studies of caloric restriction in mice and anorexia in humans have demonstrated that although these are states of lower visceral and subcutaneous fat, there is a paradoxical increase in bone marrow adipose tissue [224,225]. Clearly, marrow fat is acting distinctly from other fat depots, although the physiologic function of marrow fat is not known. Given the proximity to bone, marrow fat may play a role in skeletal physiology. Most of the literature on marrow fat and bone demonstrates a negative association, such that those with higher marrow fat have lower BMD [226]. This has been illustrated in both sexes, at various ages, and in those with and without

osteoporosis [227,228]. Increased marrow fat may exert negative skeletal through multiple mechanisms. First, marrow adipocytes and osteoblasts share a common mesenchymal stem cell precursor within the marrow. Marrow adipogenesis may occur at the expense of osteoblastogenesis. Second, secreted factors from adipocytes, such as adipokines, fatty acids, and cytokines, may negatively affect bone in the local environment.

Interest in marrow fat as a mediator of skeletal health, including after bariatric surgery, has been emerging in recent years. Marrow fat changes after bariatric surgery appear to vary with procedure type. Generally, marrow fat has been reported to be stable or mildly decreased after RYGB [49,51,229–231] and increased after sleeve gastrectomy [49,50]. The mechanisms for procedure-specific differences are unclear, but differences underscore the distinct regulation of marrow fat in the setting of dramatic subcutaneous and visceral fat loss.

Marrow fat studies may also provide insight into the pathophysiology of other metabolic diseases, such as type 2 diabetes, which is associated with an increased risk of fracture [232]. In a study of 30 women with obesity undergoing RYGB, effects of RYGB on longitudinally assessed marrow fat differed by diabetes status, women with diabetes demonstrated a decrease in vertebral marrow fat, whereas women without diabetes had stable marrow fat levels [229]. Changes in hemoglobin A1c and marrow fat were correlated, meaning those who had greater declines in A1c had further decreases in marrow fat. This is consistent with the general finding that type 2 diabetes may be a state of increased marrow fat [233]. Another study did not find marrow fat differences by diabetes status after RYGB [230].

## 4. Prevention and treatment of skeletal effects

### 4.1 Universal recommendations

Professional organizations have issued guidelines for the peri- and postoperative care of the bariatric surgery patient, including those that aim to decrease the risk of skeletal complications of surgery. These references include Clinical Practice Guidelines published by the Endocrine Society in 2010 [106]; Clinical Practice Guidelines issued jointly by the American Association of Clinical Endocrinologists (AACE)/American College of Endocrinology (ACE), The Obesity Society (TOS), the American Society for Metabolic and Bariatric Surgery (ASMBS), the Obesity Medicine Association, and the American Society of Anesthesiologists with most recent update in 2019 [11]; a Position Statement from the ASMBS specifically about metabolic bone changes [234]; and a Position Statement from the European Calcified Tissue Society (ECTS) [24]. Based on the best

**TABLE 59.3** Skeletal health recommendations before and after bariatric surgery.

Before surgery	Check 25(OH)D and replete low levels DXA based on age-appropriate screening Consider DXA in select patients including postmenopausal women and older men
After surgery	
Supplementation	Calcium 1200–1500 mg/day as chewable citrate Consider higher doses for BPD-DS Vitamin D 3000 IU, titrate to >30 ng/mL
Biochemical monitoring	Calcium, albumin, phosphorus, parathyroid hormone, 25(OH)D after 3 months, then every 6–12 months Consider 24-h urinary calcium if additional data needed
BMD monitoring	DXA based on age-appropriate screening; consider in others after 2 years

BMD, bone mineral density; BPD-DS, biliopancreatic diversion with duodenal switch; DXA, dual-energy X-ray absorptiometry.

Modified from AACE/TOS/ASMBS/OMO/ASA, ECTS, and Endocrine Society clinical practice guidelines.

available data, the recommendations are notably limited by a paucity of randomized controlled trials (RCTs) with BMD or fracture outcomes. Our adaptations of these recommendations are listed in [Table 59.3](#).

Preoperative screening of 25(OH)D and PTH levels, with the preoperative treatment of vitamin D and calcium deficiencies, is recommended for patients preparing to undergo any bariatric surgical procedure. Postoperatively, routine supplementation with calcium and vitamin D is also universally recommended. The AACE/TOS/ASMBS/OMO/ASA guidelines specify that calcium supplementation should be with calcium citrate in divided doses, such that elemental calcium intake is 1200–1500 mg/day (from diet plus supplements) for adjustable gastric band, sleeve gastrectomy, and RYGB, whereas supplementation after BPD-DS should include calcium at 1800–2400 mg/day [234]. The same guidelines state that minimum vitamin D intake is 3000 IU daily, as vitamin D<sub>3</sub>, titrated to achieve 25(OH)D levels at least 30 ng/mL. The ECTS suggests calcium 1200–1500 mg/day and vitamin D 400–800 U/day [24].

Postoperative laboratory surveillance recommendations include serum calcium, albumin, 25(OH)D, and PTH levels at a minimum of annually [234]; many also recommend lab surveillance at 3 months and/or 6 months postoperatively. The AACE/TOS/ASMBS/

OMO/ASA guidelines also recommend consideration of measuring 24-h urinary calcium and biochemical markers of bone turnover.

Professional organizations have differed in their recommendations about BMD assessment by DXA, in light of the absence of evidence about the utility of such screening. The Endocrine Society suggests preoperative DXA in all bariatric patients, and DXA yearly until stable after BPD-DS and RYGB, with the consideration of yearly DXA after sleeve gastrectomy and adjustable gastric banding [106]. The ECTS encourages DXA screening in all postmenopausal women and men 50 years old and older before bariatric surgery [24]. The AACE/TOS/ASMBS/OMO/ASA guidelines recommend consideration of DXA at baseline and 2 years post-op in those who have had RYGB or BPD-DS [11]. All bariatric surgery patients should undergo DXA based on age-appropriate recommendations of the Bone Health and Osteoporosis Foundation [235] or the United States Preventive Services Task Force [236].

In addition to these recommended measures, other strategies to consider in the bariatric surgery patient are those that have been shown to attenuate—although not prevent—the loss of the bone mass associated with nonsurgical weight loss in older adults. Exercise, and particularly weight-bearing and muscle-loading exercise, mitigates an increase in bone resorption and decline in BMD when added to caloric restriction [237,238] or when pursued after bariatric surgery [239]. Higher protein intake also attenuates decline in BMD in older adults undergoing caloric restriction [240]. A randomized controlled trial tested the effect of a prebiotic intervention on intestinal fractional calcium absorption in postmenopausal women who previously underwent RYGB [241]. While there was no between-group difference in change in FCA, nor in calciotropic hormones or bone turnover markers, those with greater change in microbial composition following prebiotic treatment had greater increase in FCA, suggesting that manipulation of the gut microbiome may hold potential as an intervention.

An RCT of a multipronged intervention of exercise, calcium, vitamin D, and protein supplementation was shown to attenuate—although not prevent entirely—postoperative increases in bone turnover markers and declines in BMD after RYGB and sleeve gastrectomy [38]. In this trial, the intervention consisted of the combination of 28,000 IU vitamin D<sub>3</sub> weekly for 8 weeks before surgery, 16,000 IU vitamin D<sub>3</sub> weekly with 1000 mg calcium citrate daily after surgery, daily protein supplementation, and daily physical exercise including walking and strength training. The control group received no preoperative vitamin D, no postoperative supplementation with calcium, vitamin D, or

protein, and no obligatory physical exercise. Additional research is needed to identify the relative importance of each of the components of that multipronged intervention.

## 4.2 Management of osteoporosis after bariatric surgery

For those who have had bariatric surgery and are found to be osteoporotic, there is very little evidence to inform management. Antiresorptive agents (bisphosphonates or denosumab) should only be considered in patients after bariatric procedures with osteoporosis once adequate calcium intake and vitamin D status have been confirmed and are stable [11]. This is critical given the elevated risk for bone disease and diminishing supplement adherence with time.

The AACE/TOS/ASMBS/OMO/ASA guidelines caution that if antiresorptive therapy is indicated after bariatric procedures, then intravenously administered bisphosphonates should be used, as concerns exist about adequate oral absorption and potential anastomotic ulceration with orally administered bisphosphonates [11]. If concerns about absorption or potential anastomotic ulceration are obviated, the guideline authors state that oral bisphosphonate administration could be considered. A pilot randomized trial of monthly oral risedronate for the 6 months after surgery showed promise to reduce areal BMD loss after sleeve gastrectomy [242]. However, the ECTS recommends an injectable bisphosphonate as the first-choice treatment and denosumab as second choice [24]. Further research is needed to guide osteoporosis management in this unique patient population.

## 5. Summary points

- Bariatric surgery is an effective treatment for severe obesity. The sleeve gastrectomy and Roux-en-Y gastric bypass are the most commonly performed bariatric procedures.
- After bariatric surgery, there are increased bone turnover, decreased bone mineral density, and diminished bone microstructure. These detrimental skeletal effects are most clearly documented after the Roux-en-Y gastric bypass procedure, with increasing evidence about sleeve gastrectomy.
- Fracture risk increases after the malabsorptive bariatric procedures.
- Potential mechanisms for bone loss after bariatric surgery include nutritional deficiencies; the mechanical unloading of the bone; muscle loss; and

changes in adipokines, sex steroids, gut hormones, and bone marrow adipose tissue.

- Vitamin D deficiency is common after bariatric surgery, and therefore, routine supplementation is recommended.
- Intestinal calcium absorption decreases after Roux-en-Y gastric bypass and sleeve gastrectomy, despite optimization of vitamin D status.
- Professional guidelines offer recommendations about supplementation and skeletal health monitoring, but more supporting evidence is needed to solidify the best clinical practices.

# Genetic determinants of 25-hydroxyvitamin D concentrations

*Elina Hyppönen<sup>1</sup>, Ang Zhou<sup>1</sup> and Karani S. Vimalleswaran<sup>2</sup>*

<sup>1</sup>Australian Centre for Precision Health, University of South Australia, Adelaide, SA, Australia <sup>2</sup>Department of Food and Nutritional Sciences, University of Reading, Reading, United Kingdom

## OBJECTIVES

- Present evidence for the role of genetic variation in affecting serum 25(OH)D concentrations.
- Summarize information on variants that have been associated with 25(OH)D concentrations and the possible role these may have in the metabolic vitamin D pathway.
- Discuss practical implications and possible uses of information on genetic determinants of 25(OH)D concentrations.

with estimates as high as 86% reported by some studies [1–4]. However, heritability that can be explained by GWAS (single nucleotide polymorphism–based “SNP” heritability) remains relatively low (around 13%–16%), despite the largest of the studies identifying several independent variants associated with 25(OH)D concentrations [5,6]. In this chapter, we review and describe the key genetic variants associated with 25(OH)D. We focus on genes for which the association has been replicated in independent studies, for many of which we have evidence for a role in the canonical vitamin D pathway.

## 1. Introduction

Vitamin D status (measured by serum concentrations of 25-hydroxyvitamin D, 25(OH)D) is determined by time-of-year and other, largely modifiable, factors that affect either skin synthesis or dietary intake. However, the prevalence of low 25(OH)D concentrations is sometimes high even in sunny locations and in the absence of an obvious behavioral or environmental explanation for the low concentrations. This has accelerated the interest into research on genetic determinants of 25(OH)D, with genome-wide association studies (GWASs) identifying an increasing number of variants. Heritability estimates from twin studies suggest a considerable genetic contribution to the variability in 25(OH)D concentrations,

## 2. 25(OH)D synthesis and metabolism

Most of vitamin D is obtained through skin synthesis catalyzed by ultraviolet B (UVB) radiation exposure, while it can also be obtained through diet or supplements. To obtain the biologically active metabolite 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D), vitamin D undergoes two steps of hydroxylation, primarily in the liver and kidney (see Chapter 4 and Chapters 8 and 9). As circulating levels of 1,25(OH)<sub>2</sub>D are under tight homeostatic regulation, 25(OH)D concentrations, which reflect vitamin D intakes during the past 3–4 weeks, are considered as the best measure of vitamin D status [7]. Given the important role of sunlight-induced vitamin D synthesis, 25(OH)D concentrations follow strong seasonal patterns, typically peaking in late summer, and with a trough in late winter/early spring. Indeed, differences in the skin synthesis of vitamin D

are also believed to explain the ethnic differences in skin color. Eumelanin, which provides the pigmentation for darker skins, acts as a natural sunscreen, while more efficient vitamin D synthesis in the lighter skin void of this is likely to reflect an adaptation resulting from migration to less sunny climates during the evolution. As described in Chapter 2, evolutionary genetic adaptations have responded to the dual challenge of protection against high levels of UV radiation and allowing for the photosynthesis of vitamin D. Genes affecting human skin coloration such as *OCA2*, *MC1R*, or *SLC24A4* have, therefore, great interest as candidates for influencing serum 25(OH)D concentrations. However, large-scale GWASs, which have been largely conducted in ethnically homogenous populations (typically white Europeans), did not pick up any of these skin coloration variants as key signals, and even candidate gene studies have often failed to detect related effects. This may be as some of these variants (for example, selected SNPs in *SLC24A5* in Europeans) are so strongly favored that they achieve ~100% frequency in the population [8]. Therefore, while these variants are likely to have a strong effect on vitamin D production, and hence serum 25(OH)D, they will remain undetectable until suitably powered transethnic analyses.

### 3. Heritability of serum 25(OH)D levels

Twin- and family-based studies suggest that genetics contribute substantially to circulating 25(OH)D concentrations [1–4]. Typically, these estimates are derived from comparisons of intraclass correlation (ICC) observed in monozygotic (MZ) twins to that of dizygotic twins (DZ), providing the first impression of the magnitude of the genetic influence. Heritability can also be estimated from unrelated individuals using genome-wide genotyping data (i.e., SNP heritability). However, SNP heritability estimates only capture additive genetic effects, while any nonadditive genetic effects (such as dominance and epistasis) will be neglected [9]. In the largest GWAS analysis to date using data from over 400,000 white Europeans, SNP heritability for serum 25(OH)D concentrations was estimated to be 13%–16%, depending on estimation approach [5,6]. This corresponds to the lowest estimates seen with overall twin heritability, where some studies suggest values up to 86% [10–12]. However, it is important to appreciate that heritability is not a fixed entity, and it depends on the population in which it is estimated and can vary by differences in both genetic background and the environment [13]. For serum 25(OH)D concentrations where UVB radiation dominates as the determinant of circulating concentrations during summer, heritability estimates are strongly affected by season, and 25(OH)D

levels are reported to be highly heritable in winter, with little heritability seen in summer (70% versus ~0%) [11]. Most heritability estimates are based on European ancestry populations, while studies in non-European populations have been limited. A twin study in Hispanics and African Americans, which included data from California, Texas, and Colorado ( $n = 1530$  individuals from 130 families), reported heritabilities of 23%, 28%, and 41%, respectively, for 25(OH)D levels [14]. These differences were broadly reflective of differences in geographical location, such that the higher the latitude (and the less sunlight exposure), the higher the estimated heritability.

To date, there have been only two studies in Asians; one in 109 Chinese twin pairs, which reported a heritability of 69% for 25(OH)D [15], and another one in 1126 Korean male adult twins and family members, which reported a heritability of 51% [16]. These estimates in Asian population were lower than those observed for Caucasians (86%) [12], but higher than those estimated for Hispanics (23%–41%) [14] or African Americans (28%) [14]. These studies may suggest ethnic differences in genetic influences on vitamin D status. However, we cannot exclude the role of differences in the size of the study populations, season, latitude, or other confounding factors, which might explain such ethnic discrepancy. Hence, further heritability studies need to be conducted in ethnically diverse populations living in the same area/latitude and measured the same time of year, to confirm ethnic differences in the heritability of 25(OH)D concentrations.

### 4. Genome-wide association studies of 25(OH)D

GWASs use information across many genomes to test hundreds of thousands of genetic variants to find polymorphisms that are statistically associated with the trait of interest [17]. There are now multiple published GWASs seeking to identify SNPs associated with 25(OH)D [5,6,18–36], although many of these studies have used overlapping samples. Most of the studies only include adult participants of white European ancestry [5,6,20,24,26,30,32]. There are relatively limited data from transethnic analyses [25], and only small studies have been conducted using data from African Americans ( $n = 697$  in the discovery sample) [33], Hispanic ( $n = 229$ ) [19], and Asian populations ( $n = 1387$  to 7590) [23,31,36]. There are also some small GWASs on children/toddlers [21,22,28,29,35], which, however, have largely simply confirmed some of the strongest associations seen in adults.

Three loci, including *DHCR7*, *CYP2R1*, and *GC*, have been consistently reported across European [5,6,18,20,24,26,30,32,34] and several non-European

GWASs [21,23,25,27–29,31,33,35,36]. This is in accordance with the existing evidence of the involvement of their corresponding proteins in vitamin D metabolic pathway. *DHCR7* gene encodes the enzyme 7-dehydrocholesterol reductase, which converts dehydrocholesterol to cholesterol in the skin, thereby affecting the level of substrates required for the synthetic pathway of vitamin D<sub>3</sub>, a precursor of 25(OH)D [37] (Fig. 60.1). Cytochrome P-450 family 2R1, encoded by *CYP2R1* gene, is the key 25-hydroxylase in the liver, which converts vitamin D to 25(OH)D. In the circulation, 25(OH)D is transported by the vitamin D-binding protein (encoded by *GC*) to the kidney, where it is further hydroxylated to form 1,25(OH)D, the functional active form of vitamin D. In addition to these three replicated signals, GWASs conducted on non-European cohorts have also reported several novel loci, which have not been identified in GWASs on white European ancestry. Most of those novel loci have not been independently confirmed, and many have no clear link with vitamin D metabolic pathway, requiring replication in larger samples of respective ethnic groups. Among the suggested novel loci, notable is *CYP2J2*, which was discovered in a multiethnic Asian cohort study consisting of 942 pregnant women of Malay, Indian, and Chinese ancestry [35]. *CYP2J2* encodes the enzyme cytochrome P-450 family 2, subfamily J, and polypeptide 2, which has previously been shown in vitro to hydroxylate

vitamin D [38]. It is potentially interesting that this variant has not been identified in GWASs on white European Ancestry as an influence on 25(OH)D concentrations, a difference that is not explained by frequency of allele distribution (minor allele frequency 29.5% in Asians versus 25.1% in Europeans).

### 5. Variants with evidence for replicated association with 25(OH)D

In the largest-to-date GWAS, loci that affect 25(OH)D concentrations were enriched in genes in the canonical vitamin D metabolic pathway, sulfonation, and glucuronidation pathways (which conjugate sulfur containing molecule and glucuronide to 25(OH)D for excretion and/or recycling), lipid and lipoprotein pathways, and pathways related to skin properties, implicating liver, brain, and skin as the top three locations where 25(OH)D-associated loci may exert their actions [6]. In this section, we provide further details for 35 SNPs that were identified as top hits in this genome-wide association scan in the UK Biobank [6] and that also were associated with serum 25(OH)D concentrations in the SUNLIGHT consortium in a consistent direction [6,26,39] (Table 60.1). These variants are a section of total 143 SNPs associating with 25(OH)D in the UKB GWAS analyses. Variants that could not be replicated in the

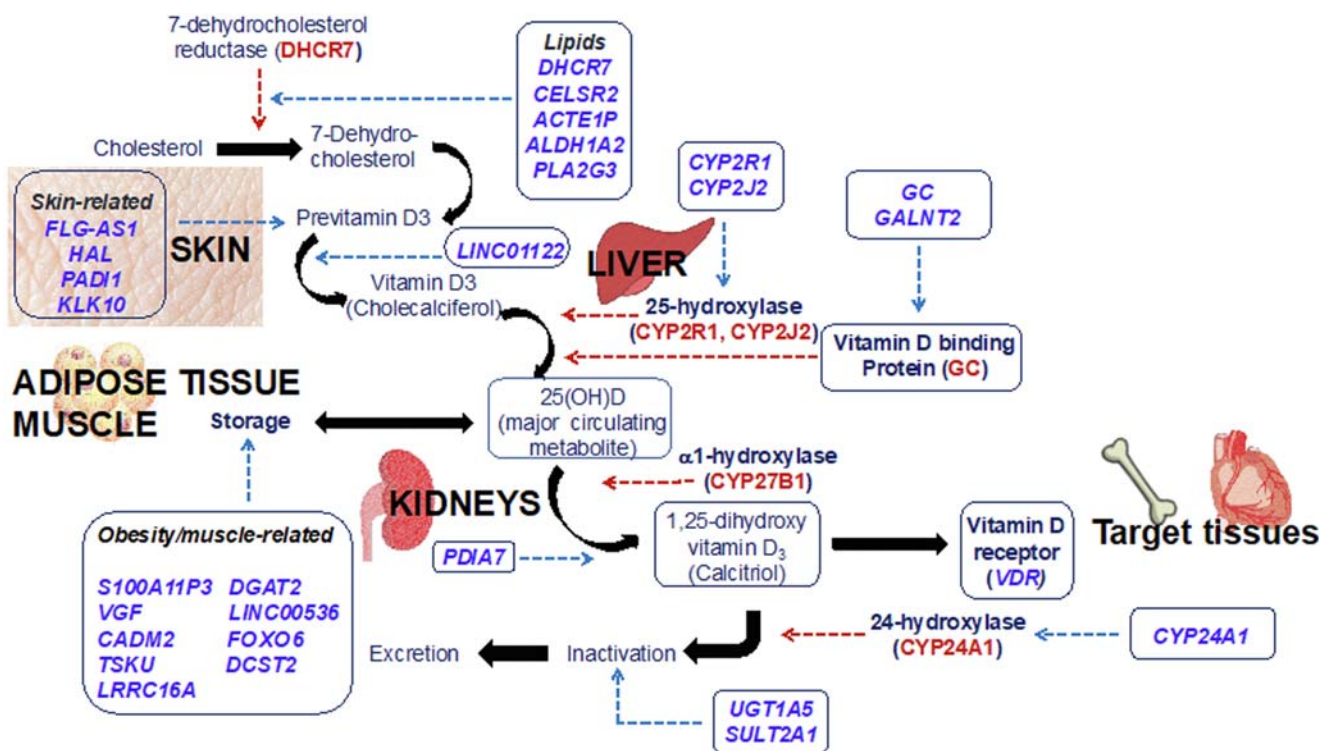

FIGURE 60.1 Possible role of the SNPs in the vitamin D pathway.

A1, serum-25(OH)D-increasing allele; A2, alternative allele; A1F, allele frequency for A1; BP, base-pair position; CHR, chromosome number; GRCh37, genome reference consortium human build 37; SNP, single nucleotide polymorphism; SE, standard error.

SUNLIGHT consortium meta-analyses as directly relevant for 25(OH)D concentrations included several that are pleiotropic (i.e., affect multiple traits) and/or are known to affect cholesterol metabolism (e.g., *PCSK9*, *LIPC*, *ABCA1*, *CETP*, *APOE*, *APOB*, *APOC1*, *LIPG*, and *LDLR*). Indeed, one reason that may explain differences between the UK Biobank and SUNLIGHT consortium meta-analysis is that the latter analyses were adjusted for body mass index, which would have prevented some of the adipose tissue-related variants (that may associate with 25(OH)D concentrations through related pathways) from being detected. In the following description and in Fig. 60.1, we describe the possible connections of the replicated variants with vitamin D metabolism. However, despite replicating evidence from two separate sources, SNPs listed in the following may not be causative, and for many cases, the connection, which we have identified with some aspect of vitamin D metabolism/function based on literature available to date, may not fully describe the connection with 25(OH)D concentrations. Therefore, these should be considered primarily as “SNPs of interest,” and where relevant, reflective of possibly interesting target genes for functional studies aiming at characterizing the cellular or physiological contexts of the genetic architecture of 25(OH)D.

**SNP rs6671730:** SNP rs6671730 is an intronic variant (G > A) in the Peroxisomal Biogenesis Factor 10 (*PEX10*) gene (chromosome location: 1p 36.32), which encodes a protein involved in import of peroxisomal matrix proteins. Mutations in *PEX10* gene have led to phenotypes relating to Zellweger syndrome [40], and one of the symptoms of the syndrome includes osteopenia [41], for which vitamin D supplementation has been the treatment. Even though the SNP rs6671730 is an intronic variant, given that alternative splicing has been reported in *PEX10* gene leading to different isoforms of the gene [42], it is possible that the SNP could have a functional impact on *PEX10* gene expression, leading to vitamin D deficiency and resulting in bone-related diseases.

**SNP rs35408430:** SNP rs35408430 is an intronic variant (C > T) in the peptidyl arginine deiminase 1 (*PADI1*) gene (chromosome location: 1p 36.13) that encodes a member of the peptidyl arginine deiminase family of enzymes, which catalyze the posttranslational deimination of proteins by converting arginine residues into citrullines in the presence of calcium ions [43]. As deimination by PADIs is considered a crucial event in epidermal differentiation [44], the connection of the SNP with serum 25(OH)D concentration may be through its influence on skin properties [6].

**SNP rs7522116:** SNP rs7522116 (C > T) is located in the intronic region of the forkhead box O6 (*FOXO6*) gene (chromosome location: 1p 34.2), which encodes a

protein that has been predicted to enable DNA-binding transcription factor activity, RNA polymerase II-specific and RNA polymerase II cis-regulatory region sequence-specific DNA binding activity [45]. It is expressed in the liver, skeletal muscle, and the brain, with abnormal expression associated with metabolic disease, cancer, and altered lifespan [46]. FoxO6 is an important regulator of insulin-stimulated gluconeogenesis in the liver [47], and FoxO6 expression has been demonstrated to be significantly downregulated in the brain of dietary obese mice [48]. Hence, it is possible that the impact of the *FOXO6* on 25(OH)D could have been mediated through its link with obesity and insulin resistance (see Chapter 75).

**SNP rs7528419:** SNP rs7528419 (A > G) is located in the 3'-UTR region of the cadherin EGF LAG seven-pass G-type receptor 2 (*CELSR2*) gene (chromosome location: 1p 13.3), which encodes a protein that has been shown to be a receptor involved in contact-mediated communication, with cadherin domains acting as homophilic binding regions and the EGF-like domains involved in cell adhesion and receptor-ligand interactions [49]. SNP rs12740374 in the *CELSR2* gene has been identified as a causal variant for liver-specific modulation of the expression of *SORT1* (sortilin 1) gene [50], which has been shown to be associated with low-density lipoprotein cholesterol levels and coronary heart disease [51]. Given the biological link between vitamin D and lipid metabolic pathway [52], it is possible that the SNP rs7528419 could act as a proxy for the SNP rs12740374 in the *CELSR2* gene, which may partly explain the association between SNP rs7528419 and 25(OH) D concentration.

**SNP rs1933064:** The SNP rs1933064 (G > A) is an intronic variant in the FLG antisense RNA 1 (*FLG-AS1*) gene (chromosome location: 1q21.3), an RNA gene that is affiliated with the long noncoding RNA (lncRNA) class. Skin pigmentation-related diseases such as ichthyosis vulgaris [53] and peeling skin syndrome 6 [54] have been shown to be associated with *FLG-AS1*. It has been suggested that the SNP rs1933064 may link to serum 25(OH)D concentration through its influence on dermal integrity [6].

**SNP rs76798800:** SNP rs76798800 (G > T) is located in the intronic region of the DC-STAMP domain containing 2 (*DCST2*) gene (chromosomal location: 1q21.3), which encodes a protein product that is predicted to be integral component of membrane. *DCST2* has been identified as an important regulator of osteoclast cell fusion in bone homeostasis [55], which may provide some link to vitamin D [56], but the role of this SNP rs76798800 on vitamin D status is yet to be established. In addition, genetic variant in *DCST2* gene has been shown to be associated with early length and adult height [57], which is suggestive of its possible relationship with vitamin D.

**SNP rs6672758:** SNP rs6672758 (C > T) is an intronic variant in the polypeptide *N*-acetylgalactosaminyltransferase 2 (*GALNT2*) gene (chromosomal location: 1q42.13), which encodes a member of the glycosyltransferase 2 protein family that is involved in O-linked glycosylation of the immunoglobulin A1 hinge region and has been shown to influence triglyceride levels [58] and associated with type 2 diabetes [59], blood pressure [60], and cancer [61]. In addition, the *GALNT2* SNP rs6684432 showed an association with serum vitamin D-binding protein concentrations [62]; even though the *P* value for the association did not reach genome-wide significance, the association could be biologically plausible given that the protein transcripts may be involved in posttranslational modification of vitamin D-binding protein [63], which is likely to affect vitamin D binding, transport, or metabolism. Further molecular studies are warranted to confirm this association.

**SNP rs727857:** SNP rs727857 (G > A) is located in the intronic region of long intergenic nonprotein coding RNA 1122 (*LINC01122*) gene (chromosomal location: 2p16.1), which is an RNA gene that is affiliated with the lncRNA class [64]. A recent study using bioinformatic pathway enrichment analysis has shown that *LINC01122* gene was one of the 989 differentially expressed genes, which was significantly enriched in the vitamin D<sub>3</sub> biosynthesis [65], suggesting the possible biological link between SNP rs727857 and vitamin D status.

**SNP rs1047891:** SNP rs1047891 (C > A) is a missense variant in the carbamoyl-phosphate synthase 1 (*CPS1*) gene (chromosomal location: 2q34). The gene encodes the mitochondrial enzyme that catalyzes synthesis of carbamoyl phosphate from ammonia and bicarbonate [66]. While this SNP rs1047891 is associated with serum 25(OH)D levels with evidence for replication [67], the molecular link between the SNP and vitamin D needs to be established.

**SNP rs2012736:** SNP rs2012736 (C > A) is a missense variant in the UDP glucuronosyltransferase family 1 member A5 (*UGT1A5*) gene (chromosomal location: 2q37.1), which encodes the UDP-glucuronosyltransferase, an enzyme that transforms small lipophilic molecules, such as steroids, bilirubin, hormones, and drugs, into water-soluble, excretable metabolites [68]. Related isoenzymes have been identified as catalysts for 25(OH)D<sub>3</sub> glucuronidation in the human liver, providing a possible link between this SNP and 25(OH)D concentrations [69].

**SNP rs6782190:** SNP rs6782190 (G > A) is an intronic variant in the cell adhesion molecule 2 (*CADM2*) gene (chromosomal location: 3p 12.1), which encodes a member of the synaptic cell adhesion molecule 1 family [70]. Animal studies have established an association between *CADM2* and metabolic traits, including obesity [71],

suggesting that the SNP could influence serum vitamin D concentrations through its effect on obesity and storage capacity of 25(OH)D.

**SNP rs705117:** SNP rs705117 (A > G) is located in the intronic region of the vitamin D-binding protein (*GC*) gene (chromosomal location: 4q13.3), which encodes a protein that binds to vitamin D and its plasma metabolites and transports them to target tissues [72]. Despite being an intronic variant, the SNP rs705117 was identified to be one of the top hits for serum vitamin D-binding protein concentration in the genome-wide association scans [62], suggesting that the SNP could be a proxy for a functional genetic variant.

**SNP rs1352846:** SNP rs1352846 (A > G) is another intronic variant in the *GC* gene. Given that alternative spliced transcript variants encoding different isoforms have been identified for the *GC* gene and intronic variants can impact alternative splicing by interfering with splice site recognition [73], further studies investigating the role of the intronic variants in the alternative splicing of *GC* gene are warranted.

**SNP rs78151190:** SNP rs78151190 (A > C) is an intronic variant located in the capping protein regulator and myosin 1 linker 1 [*CARMIL1* (also called as *LRRCL16*)] gene (chromosomal location: 6p 22.2), which encodes a protein that has been shown to play a role in actin filament network formation, plasma membrane-bounded cell projection organization, and positive regulation of cellular component organization [74]. About 10% of muscle tissue consists of actin, and as alongside with adipose tissue muscle is a key storage site for 25(OH)D [75] (see Chapter 29), this might explain the link with 25(OH)D concentrations.

**SNP rs75741381:** SNP rs75741381 (C > G) is located in the intronic region of the VGF nerve growth factor inducible (*VGF*) gene (chromosomal location: 7q22.1), which encodes a protein that is expressed in neuroendocrine cells and is upregulated by nerve growth factor [76]. *VGF* has been linked with appetite control [77], and animal studies have shown that it is required for diet-induced obesity to develop [78], suggesting a link through variation in the ability to store 25(OH)D.

**SNP rs12056768:** SNP rs12056768 (T > G) is an intronic variant in the long intergenic nonprotein coding RNA 536 (*LINC00536*) gene (chromosomal location: 7q22.1), which is an RNA gene that is affiliated with the lncRNA class. *LINC00536* has been shown to interact with the Wnt3a/β-catenin signaling in the context of its influence on malignant phenotypes of bladder cancer cells [79]. As Wnt/β-catenin signaling is emerging as an important signaling pathway in regulating adipose tissue lipogenesis [80], the association of the SNP rs12056768 with serum 25(OH)D concentration may be mediated through its influence on adipogenesis, affecting the storage of 25(OH)D.

**SNP rs77532868:** SNP rs77532868 (C > T) is located in the intron of glutamate ionotropic receptor delta-type subunit 1 (*GRID1*) gene (chromosomal location: 10q23.1–q23.2), which encodes a subunit of glutamate receptor channels that mediate the fast excitatory synaptic transmission in the central nervous system and play key roles in synaptic plasticity [81]. Animal studies have shown that vitamin D deficiency can accelerate age-related cognitive decline by inhibiting synaptic transmission [82]. Hence, it is possible that the *GRID1* gene could be a target for calcitriol in mediating the synaptic transmission. Functional studies investigating the role of genetic variants in the *GRID1* gene are required to understand the link between *GRID1* and vitamin D status.

**SNP rs12794714:** SNP rs12794714 (G > A) is a synonymous variant in the cytochrome P450 family 2 subfamily R member 1 (*CYP2R1*) gene (chromosomal location: 11p15.2). The gene encodes a member of the cytochrome P450 superfamily of enzymes, which catalyze several reactions involved in the synthesis of cholesterol, steroids, and other lipids. In addition, the enzyme is a vitamin D hydroxylase that converts vitamin D into the 25(OH)D [83]. Several GWASs have identified SNP rs12794714 as one of the top signals for 25(OH)D levels [19,20,26], reflecting the link of this cytochrome P450 enzyme in the synthesis of 25(OH)D.

**SNP rs61891388:** SNP rs61891388 (T > G) has been mapped to the genes, *TMEM151A* and *CD248* (chromosomal location: 11q13.2) [84]. *TMEM151A* has been predicted to be an integral component of membrane, and *CD248* has been shown to enable extracellular matrix binding activity and extracellular matrix protein binding activity in addition to its role in the positive regulation of endothelial cell apoptotic process. Given that active hormonal vitamin D plays an important role in triggering apoptosis in epithelial cancer cells [85], the link between vitamin D and *CD248* is biologically plausible. However, the possible mechanism by which this variant associates with 25(OH)D is yet to be established.

**SNPs rs1660839 and rs12803256:** The SNP rs1660839 (G > A) and rs12803256 (A > G) have been mapped to the gene Actin Epsilon 1, Pseudogene (*ACTE1P*), which is located at chromosome 11q13.4. The gene is an RNA gene and is affiliated with the lncRNA class. The SNP rs12803256 has also been reported as a GWAS signal for vitamin D deficiency in Korean cohorts involving 7590 participants [31]. Both *ACTE1P* [86] and vitamin D [87] have been shown to be involved in the etiology of adolescent idiopathic scoliosis, which is an abnormal curvature of the spine that appears in adolescence, suggesting a possible role of *ACTE1P* in bone health. *ACTE1P* rs12803256 is located in proximity of the *DHCR7* locus (0.01 Mb upstream), and the association

of the SNP with 25(OH)D concentrations may be explained through its links to *DHCR7* function [31].

**SNP rs12798050:** SNP rs12798050 (C > T) has been mapped to the *S100A11* pseudogene 3 (*S100A11P3*) gene (chromosomal location: 11q13.4), which is also called as *S100* calcium-binding protein A11 pseudogene 3. The family members of *S100* proteins have been shown to play multiple roles in buffering calcium ion concentration, participating in energy metabolism, regulating cell proliferation and differentiation, and acting as signaling molecules to activate their corresponding receptors to participate in innate and acquired immune responses [88]. Given the role of vitamin D in calcium absorption [89], energy metabolism [90], cell differentiation [91], and immune system [92], the SNP might have an impact on influencing 25(OH)D levels.

**SNP rs72997623:** SNP rs72997623 (C > A) is an intronic variant in the diacylglycerol O-acyltransferase 2 (*DGAT2*) gene (chromosomal location: 11q13.5), which encodes an enzyme that catalyzes the final reaction in the synthesis of triglycerides in which diacylglycerol is covalently bound to long-chain fatty acyl-CoAs [93]. *DGAT* affects adipose tissue formation [94], and mutations in the *DGAT2* have been shown to be associated with obesity [95], suggesting that it may contribute to 25(OH)D concentrations through influences on storage capacity. Animal studies have also shown that vitamin D receptor upregulates the expression of *DGAT2*, which suggests a coordinated response directed to triglyceride synthesis [96]. This has further been supported by a study that demonstrated an increase in mRNA expression of *DGAT2* in C2C12 myotubes in response to the calcitriol treatment [97].

**SNP rs1149605:** SNP rs1149605 (T > C) has been mapped to the genes, guanylate cyclase 2E, pseudogene (*GUCY2EP*) and tsukushi, small leucine-rich proteoglycan (*TSKU*) (chromosomal location: 11q13.5). *GUCY2EP* encodes a protein involved in chemosensation in rodents, and *TSKU* has been predicted to enable transforming growth factor beta binding activity and act upstream of or within several processes, including negative regulation of Wnt signaling pathway. Even though genetic variations in the Wnt/ $\beta$ -catenin pathway have been shown to be associated with metabolic diseases [98], SNP rs1149605 has not been associated with traits other than 25(OH)D concentrations in GWAS conducted to date; however, other variants in *GUCY2EP/TSKU* have been associated with wide range of metabolic and cognitive traits [99].

**SNP rs10859995:** SNP rs10859995 (T > C) is an intronic variant located in the histidine ammonia-lyase (*HAL*) gene (chromosomal location: 12q23.1), which is expressed in the skin, and is upregulated during the differentiation of keratinocytes [100]. *HAL* deaminates L-histidine to trans-uronic acid [101], which in the stratum

corneum has been shown to absorb UVB [102] and reduce the production 25(OH)D [103]. Therefore, the connection of the SNP rs10859995 with serum 25(OH)D concentration may be through its influence on skin properties [6]. In the analysis of the genotype tissue expression project datasets, one of the *HAL* SNPs, rs17676826, was shown to be significantly associated with its mRNA expression levels in sun-exposed skin of the lower leg [104] suggesting a possible role of *HAL* in influencing 25(OH)D levels in response to sun-light exposure.

**SNP rs8018720:** SNP rs8018720 (G > C) is a missense polymorphism in the Sec23 homolog A, coat complex II component (*SEC23A*) gene (chromosomal location: 14q21.1), which encodes a protein that plays a role in the ER–Golgi protein trafficking. Aside of a replicated association between this SNP and serum 25(OH)D concentration [26,31], rs8018720 has not been associated with other traits [105]. Functional links with vitamin D metabolism are yet to be established.

**SNP rs261291:** SNP rs261291 (T > C) has been mapped to aldehyde dehydrogenase 1 family member A2 (*ALDH1A2*) gene (chromosomal location: 15q21.3), which encodes an enzyme that catalyzes the synthesis of retinoic acid (RA) from retinaldehyde [106]. In addition to 25(OH)D, rs261291 has been associated with multiple lipid related traits in GWASs [107]. The exact role of rs261291 explaining the associations with 25(OH)D and lipid/cholesterol metabolism is yet to be established by functional studies.

**SNP rs77924615:** SNP rs77924615 (G > A) is an intronic variant in the protein disulfide isomerase like, testis expressed (*PDILT*—also known as *PDIA7*) gene (chromosomal location: 16p12.3), which encodes a member of the disulfide isomerase family of endoplasmic reticulum proteins that catalyze protein folding and thiol–disulfide interchange reactions [108]. In addition to 25(OH)D, GWASs suggest a link between rs77924615 with multiple renal traits (kidney stones, glomerular filtration rate, serum creatine, urate concentrations) [109–111], which may suggest a link through kidney function and 1,25-hydroxylation.

**SNP rs212100:** SNP rs212100 (T > C) is an intronic variant in the sulfotransferase family 2A member 1 (*SULT2A1*) gene (chromosomal location: 19q13.33). *SULT2A1* encodes a liver- and intestine-expressed sulfo-conjugating enzyme that is responsible for the inactivation by sulfonation of 25(OH)D [112,113], which is likely the underlying mechanism connecting this SNP with serum 25(OH)D concentration [6].

**SNP rs10426:** SNP rs10426 (G > A) is a 3' untranslated region variant in the kallikrein-related peptidase 10 (*KLK10*) gene (chromosomal location: 19q13.41), which encodes a protein that has been shown to play a role in dermal integrity [114]. It has been suggested

that the connection of the SNP with serum 25(OH)D concentration is likely through its influence on skin properties [6].

**SNPs rs6123359, rs17216707, rs2585442, and rs2762943:** The three SNPs, rs6123359 (A > G), rs17216707 (T > C), and rs2585442 (C > G), have been mapped to the genes, cytochrome P450 family 24 subfamily A member 1 (*CYP24A1*) and brain-enriched myelin-associated protein 1 (*BCAS1*), whereas the SNP rs2762943 (T > G) has been mapped to *CYP24A1* and prefoldin subunit 4 (*PFDN4*) genes (chromosomal location: 20q13.2). *CYP24A1* is an important candidate for vitamin D metabolic pathway given that the protein encoded by the gene initiates the degradation of 1,25-dihydroxyvitamin D<sub>3</sub> (i.e., physiologically active form of vitamin D<sub>3</sub>) by hydroxylation of the side chain [115]. In addition, this enzyme also plays a role in calcium homeostasis and vitamin D endocrine system [116]. Furthermore, *BCAS1* and *PFDN4* are some of the target genes for 1,25(OH)2D<sub>3</sub> in cancer cells [117,118], suggesting the possible molecular relationship between vitamin D and the target genes.

**SNP rs2074735:** SNP rs2074735 (G > C) is a missense polymorphism in the phospholipase A2 group III (*PLA2G3*) gene (chromosomal location: 20q13.2), which encodes an enzyme that functions in lipid metabolism and catalyzes the calcium-dependent hydrolysis of the sn-2 acyl bond of phospholipids to release arachidonic acid and lysophospholipids [119]. The mechanism explaining the link between SNP rs261291 and 25(OH)D is yet to be established by functional studies.

## 6. Gene–environment interaction

Gene–environment interaction (GxE) describes the phenomenon where the genetic influences of the traits are modulated by behavior or environment (or vice versa) [120]. At cellular level, this type of effect modification may be explained through epigenetic effects, such as DNA methylation, histone acetylation, and non-coding RNA expression [121], which regulate whether, or the extent to which, the effects of a gene affect the trait of interest. A recent GWAS identified 25 independent loci suggestive of GxE interaction, where the magnitude of the genetic association with 25(OH)D varied by environmental factors influencing serum 25(OH)D concentrations. Of these putative GxE loci, 23 loci were marginally associated with serum 25(OH)D concentration at the genome-wide significant level, and five loci (including *CYP2R1* and *SEC23A* and others) showed genome-wide significant interaction with season [5,6]. Interestingly, at the *CYP2R1* and *SEC23A* loci, serum 25(OH)D concentrations for the carriers of 25(OH)D-lowering allele were less responsive to season compared

with noncarriers, suggesting that some individuals may have steadily low serum 25(OH)D levels regardless of the season of measurement [5]. Further, in an earlier genome-wide GxE analysis, carriers of 25(OH)D-lowering allele at the *CYP2R1* locus also appear to be less responsive to dietary vitamin D intake [26]. A similar GxE interaction pattern has also been observed at the *GC* locus in candidate GxE interaction studies with respect to vitamin D supplementation [122], consumption of vitamin D<sub>3</sub>-fortified bread and milk [123,124] and UVB treatment [123,124]. The extent to which these GxE patterns might have practical implications, for example, by warranting more personalized approaches to vitamin D supplementation, is uncertain (as also discussed in the following).

## 7. Applications and practical implications

Findings from existing GWAS for serum 25(OH)D concentrations have highlighted genes in the canonical vitamin D metabolic pathway. These have also shown enrichment of associations near genes involved in skin synthesis, hepatic hydroxylation, sulfonation, and glucuronylation, suggesting serum levels of 25(OH)D are in cross-talk with a range of related metabolic processes [5,6]. The understanding about genetic loci associated with serum 25(OH)D concentrations has already proven their uses as instruments for studies examining the causal effect of vitamin D on other traits. Sitting at the interface between observational studies and interventional trials, Mendelian randomization (MR) has been increasingly used to strengthen causal evidence in observational studies (see Chapter 61). This approach uses genetic variants associated with the exposure of interest (so-called genetic instrument) to approximate the exposure, and conditional on the key method assumptions being met, MR has the benefit of reducing bias due to confounding and reverse causation [125]. The genetic instrument is normally selected from the genome-wide association analysis of the exposure of interest, often including all independent and genome-wide significant loci. Earlier MR analyses restricting to variants in the canonical vitamin D pathway (including *DHCR7*, *CYP2R1*, *GC*, and *CYP24A1*) have provided insight into the causal nature of the association of 25(OH)D with risks for multiple sclerosis [126], type 2 diabetes [127], and hypertension [128]. With additional loci being discovered for serum 25(OH)D [5,6], many MR studies now incorporate these new loci in the analyses. While inclusion of additional loci can bolster statistical power, it is also important to keep in mind the potential for pleiotropic effects that these variants could bring into the analysis and that could bias the MR analysis [129]. As alluded earlier in the chapter, many newly

discovered variants have less clear/unknown function related to vitamin D metabolism and are strongly related to other traits, such as BMI, cholesterol, and blood pressure, among others. Restricting analyses to variants with consistent replicating associations with 25(OH)D concentrations will help to alleviate related concerns, at least to some extent. To address potential pleiotropy, studies will need to include sensitivity analyses using different sets of variants and different analytical approaches that will help to assess the robustness of their findings. The multivariable MR analyses, which directly account for pleiotropic effects by simultaneously modeling the genetic effects on 25(OH)D and on pleiotropy-related indicators, may also be helpful. However, this is only possible if the relevant pleiotropic pathways can be hypothesized and if relevant information is available for the analyses. Rigorously conducted MR studies taking account of nonlinearity are likely to be of increasing value in the context of vitamin D research, given that like many (most) nutrients and biomarkers circulating concentrations are likely to have threshold effects, where harm is both seen at very low or high levels [130,131]. This is of great value, considering the challenge of recruiting vitamin D-deficient individuals to clinical trials to investigate the health effects of vitamin D supplementation [130,131]. Indeed, recent studies using the nonlinear or stratified MR approach suggest that vitamin D deficiency may be associated with an increased risk for CVD and all-cause mortality, both of which are not evident using the standard linear MR approach [39,132], although evidence for a beneficial role of vitamin D supplementation on mortality has been seen in RCTs [139]. Recently, this approach has also confirmed a role of vitamin D deficiency on dementia risk [133], an association which has also been reported by linear MR studies [134]. However, it is very plausible that many of the benefits may only be seen with the prevention and treatment of vitamin D deficiency, while much of the time, benefits are unlikely for further increases in concentrations for individuals who are already vitamin D replete.

Genetic correlation is another widely used genetic epidemiology approach. This allows us to quantify overlaps in genetic architecture between two traits, and it can provide a better understanding of the shared biological pathways and/or causal relationship between 25(OH)D and other traits [135]. Indeed, genetic correlation analyses using the UK Biobank vitamin D GWAS results across over 700 traits [5,6] have, for example, highlighted that serum 25(OH)D is negatively correlated with cognition-related traits, including time of computer use, educational attainment, and intelligence. Given the potential link between intelligence and years of education, and working indoors [137], this finding is likely reflective of behaviors associated with decreased level of sun exposure [6].

Genetic variants can be combined into a genetic risk score (GRS) to reflect individuals' lifetime genetic risk of disease, with an expectation that GRS may be used to predict disease risk. In the context of serum 25(OH)D, it is reasonable to expect that individuals who carry many 25(OH)D-lowering alleles as reflected by their GRS are more susceptible to a low vitamin D status. In the UK Biobank, the difference in the mean 25(OH)D between individuals in the highest versus lowest quartile of the GRS is about 9 nmol/L, if estimated based on the 35 replicated vitamin D GWAS variants [39]. The magnitude of the association is similar to that seen with self-reported use of vitamin D supplementation in the UK Biobank during winter (9.7 nmol/L) [138] and suggests that when supply from sunlight or diet is limited, people with high genetic burden will be more likely to have lower concentrations that could have clinical relevance. As noted before (see Gene–environment interaction), individuals with genetically low 25(OH)D may also be less responsive to treatments for correcting low vitamin D status [122–124]. For example, in a study using a GRS combining 2 SNPs at *CYP2R1* and *GC* loci, a ~23% increase in serum 25(OH)D after UVB treatments is seen for individuals carrying four risk alleles in contrast to a 54% increase for those carrying no risk alleles [123]. Similarly, individuals carrying four risk alleles also benefitted the least from the 6-month consumption of vitamin D<sub>3</sub>–fortified bread and milk [123]. It has also been suggested that GRS for 25(OH)D may be useful for guiding the screening and treatment for vitamin D deficiency, where individuals with a high GRS score may need to be monitored more often for serum 25(OH)D concentration, and if a low vitamin D status is detected, they may need a higher dose of vitamin D supplementation to achieve the target level. In a recent study [34], participants with serum 25(OH)D < 50 nmol/L received a tailored vitamin D supplementation recommendation based on their genetic risk. Also this study used a simple GRS consisting of 2 SNPs, one from *GC* and another from the *CYP2R1* loci, and the researchers recommended individuals with three or four 25(OH)D-lowering alleles to take 50 µg (2000IU) per day, those with 1 to 2 risk alleles to take 20–30 µg/day and those without any risk alleles 10–20 µg per day. Their GRS-based analyses suggested that recommendation to take 50 µg (2000IU) per day over 4 months was enough to reduce the gap in serum 25(OH)D concentration and prevalence of 25(OH)D < 50 nmol/L between individuals carrying three or four risk alleles and those with no risk alleles (Fig. 60.2). However, the prevalence of 25(OH)D < 50 nmol/L remained elevated for those with 2 risk alleles compared with no risk alleles. While interesting

and very promising, these results remain tentative given the increases in vitamin D intakes were achieved by recommendations, rather than placebo-controlled, blinded, and randomized provision of supplementation. The number of individuals in each of the treatment groups was also small ( $n = 10$  to  $n = 36$ ), and further trials with a larger sample are required to confirm the need, doses, and effective approaches for personalized vitamin D supplementation.

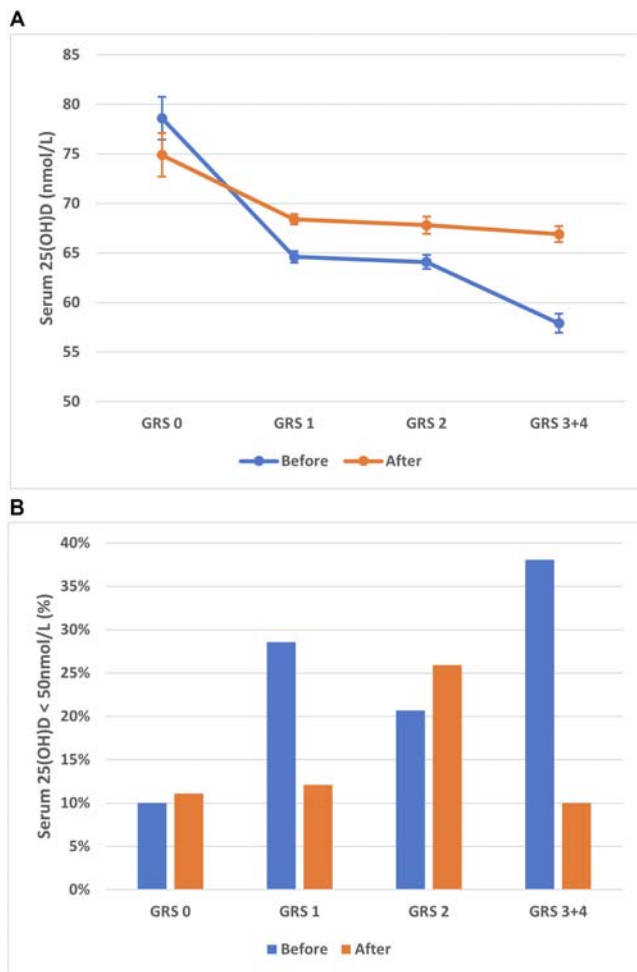

## 8. Conclusions

Genetic variants affect 25(OH)D concentrations, with heritability estimates varying depending on population and time of year. Large-scale GWASs have identified a large number of potentially interesting signals, which, in addition to the canonical vitamin D metabolism pathway, have been linked with various aspects of lipid metabolism, and pathways reflecting skin properties. These variants have provided their uses as instruments to provide genetic evidence for a causal effect of 25(OH)D, with recent applications extending these studies to investigations reflecting expected effects in the treatment of vitamin D deficiency. Further research is required to establish the benefits and uses of genetic information in guiding the need for genetically tailored personalized approaches to vitamin D supplementation and the prevention of vitamin D deficiency.

## 9. Summary points

- Twin studies suggest a considerable genetic contribution to 25(OH)D concentrations, while proportion of variability that can be explained by SNPs remains relatively low (around 13%–16%).
- There are at least 35 independent variants that have been shown to have a replicating and directionally consistent association with 25(OH)D concentrations, with variants in/near the *DHCR7*, *CYP2R1*, *GC*, and *CYP24A1* genes showing consistent associations in various population groups.
- Loci that affect 25(OH)D concentrations are largely enriched in genes in the canonical vitamin D metabolic pathway, lipid and lipoprotein pathways, and pathways related to skin properties.
- Clinical relevance of variants affecting 25(OH)D concentrations remains tentative, and while some pilot data suggests genetic differences in response to vitamin D intakes, further evidence is required to confirm the need and benefits of personalized approaches.

**FIGURE 60.2** Profile of serum 25(OH)D (A) and prevalence of serum 25(OH)D < 50 nmol/L (B) by GRS for serum 25(OH)D before and after GRS-based vitamin D supplementation reported by Sallinen et al. 2021 [34]. Genetic risk score (GRS) for serum 25(OH)D (range from 0 to 4) was calculated as the sum of the number of risk alleles for the SNPs rs4588 (A allele) in the GC locus and rs10741657 (G allele) in the *CYP2R1* locus. Participants with serum 25(OH)D < 50 nmol/L received a tailored vitamin D supplementation recommendation based on their GRS: Individuals with GRS<sub>3+4</sub> was recommended to take 50 µg (2000IU) per day, those with GRS<sub>1</sub> or GRS<sub>2</sub> to take 20–30 µg/day, and those with GRS<sub>0</sub> to take 10–20 µg per day.

## OBJECTIVES

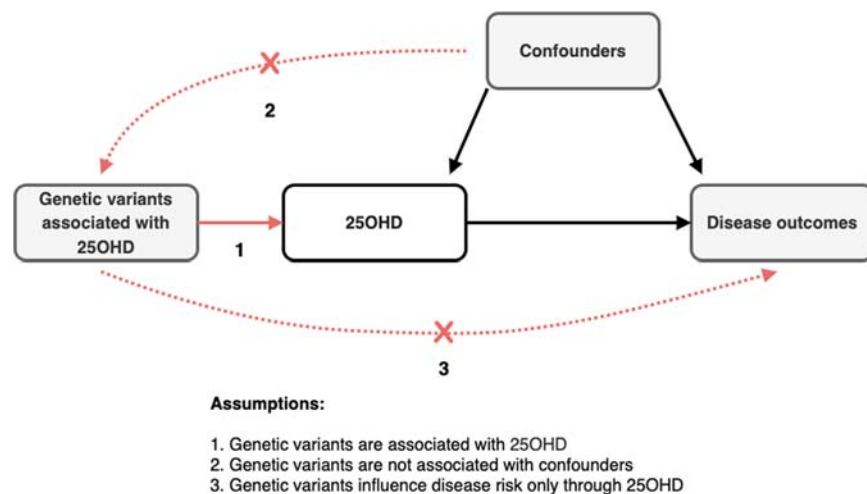

- Recognize the current knowledge gaps in the causal relationships between 25(OH)D levels and health outcomes in humans.
- Understand the basics of Mendelian randomization as a tool for causal inference.
- Present and discuss the causal evidence from Mendelian randomization studies for 25(OH)D.
- Discuss the implications of findings of Mendelian randomization studies in recommending vitamin D supplementation.

## 1. Introduction

Mendelian randomization (MR) is an established genetic epidemiological method able to test whether genetically determined levels of risk factors, such as serum 25-hydroxyvitamin D (25(OH)D) levels, are associated with disease risk [1]. There are several principles that have prompted the widespread application of MR to access causality in observational research. First, genetic variants are randomly assigned at conception in a

process similar to the randomization used in a randomized controlled trial (RCT). As such, MR limits bias due to confounding factors. This is particularly useful in the case of 25(OH)D, since it is associated with many factors that may confound its relationship with disease, such as educational attainment, body mass index (BMI), and smoking. Second, alleles are inherited at conception, which always precedes disease onset. Therefore, MR is free of bias due to reverse causation, a phenomenon where disease can influence 25(OH)D levels. This is particularly relevant since many chronic diseases can lead individuals to stay indoors more often, being less exposed to sun and having lowered 25(OH)D levels. Third, MR studies provide an assessment of a lifetime exposure to lowered 25(OH)D levels since alleles are inherited at conception.

Despite these advantages, MR studies also have important limitations, which arise mostly from the assumptions inherent to the MR design (Fig. 61.1). Given these limitations we have recently published a guideline providing readers with criteria useful for evaluating and conducting MR studies [2,3]. The first MR assumption is that the genetic variants are strongly associated with the exposure, in this case 25(OH)D levels. This can be verified by utilizing only genetic variants that have been associated at a genome-wide significant level ( $P < 5 \times 10^{-8}$ ) with 25(OH)D (see Chapter 60). The

**FIGURE 61.1** Direct acyclic graph showing illustrating the vitamin D Mendelian randomization studies and their assumptions.

second assumption is that the genetic variants are not associated with factors that confound the relationship between the exposure and the outcome. This assumption holds, as shown by the lack of association between variants in four key genes (*DHCR7*, *CYP2R1*, *GC*, and *CYP24A1*, all genes with established biological mechanisms influencing 25(OH)D levels) with potential confounders [4]. The third assumption of no (horizontal) pleiotropic relations is most challenging and failing to account for it can introduce a major bias. To properly assess the effect of genetically determined 25(OH)D on disease outcomes, the alleles that influence 25(OH)D levels must not influence risk of disease independently of 25(OH)D levels [1]. While other assumptions are required and some statistical extensions of the MR methods allow for their relaxation, it is important to bear in mind these assumptions, as they directly affect the validity of MR studies. An additional limitation of the traditional MR design is its inability to assess nonlinear effects of 25(OH)D on health outcomes, i.e., effects of low 25(OH)D levels below a threshold. In recent years, nonlinear MR studies have evolved allowing to explore causal effects of 25(OH)D levels across different cutoffs. Studies using thresholds below 50 nmol/L (defining vitamin D insufficiency) or below 25 nmol/L (defining vitamin D deficiency) have yielded contradictory results to those of traditional MR.

In this chapter, we review and discuss the evidence from the largest MR studies for 25(OH)D over the past 10 years. Despite a wealth of data supporting a role of vitamin D in human diseases in observational studies [5], evidence from large randomized control trials (RCTs) is scarce [6], with only a few exceptions [7–10]. Recent major RCTs recruiting participants with a generally better health profile, higher dosages of vitamin D supplementation, and more vitamin D replete subjects at baseline have generated mostly null results in the intention-to-treat primary outcome analysis [7–11].

Nevertheless, for many outcomes, evidence from RCT still does not exist, or the available evidence comes from small RCTs with short follow-up. Since MR can help to provide insights of the causal role of vitamin D in the etiology of common diseases, such studies can fill this knowledge gap, especially for diseases that are rare, appear later in life, and are difficult to study in RCTs.

Over 100 MR studies have evaluated the role of a life-long genetically determined 25(OH)D level on a variety of common diseases and traits [6]. To do this, MR studies have used genetic variants (single nucleotide polymorphisms [SNPs]) associated with 25(OH)D levels in genome-wide association studies (GWASs) as instruments to infer 25(OH)D serum levels. Depending on their number, these SNPs explain between 2% and 10% of the variance in 25(OH)D serum levels. Here, we are reporting results of the largest and most powered 25(OH)D MR studies for each outcome, published over the past 10 years (Table 61.1). Most of these studies are based on a two-sample MR design, where effects of the 25(OH)D SNPs on the studied outcomes are derived from cohorts that are different from the cohort from which the effects of the SNPs on 25(OH)D are generated. The two-sample MR design usually provides better statistical power compared with the one-sample MR design, in which estimates of the SNPs on both the exposure and an outcome are calculated in the same cohort. Also, the majority of the MR effects that are reported in this chapter, if not otherwise specified, correspond to the results of the inverse variance weighted (IVW) MR analysis, which is a statistically powerful MR method, albeit more susceptible to horizontal pleiotropy than approaches such as MR-Egger [93]. In most studies, results of the IVW MR method were confirmed by other MR methods (such as the MR-Egger [94], weighted median [95], and weighted mode [96]), which all aim to reduce potential horizontal pleiotropy.

**TABLE 61.1** List of Mendelian randomization studies for vitamin D, ordered by date of publication (PMID).

Study	Genetic instruments	No./No. of events	Outcomes	Estimate of effect(95% CI)	P Value	Unit of estimated effect

The concordance between MR studies of 25(OH)D levels and RCTs of vitamin D supplementation with multiple outcomes is striking, while diverging from the findings of observational studies. This supports the contention that MR studies are better suited than observational studies to understand the effect of 25(OH)D levels on risk of disease. Nevertheless, most RCTs and MR studies have been undertaken in individuals from the general population in which the prevalence of severe vitamin D deficiency is low. Most available MR studies have mostly reported null results, but as mentioned before, their design is handicapped by their inability to study nonlinear effects of 25(OH)D levels. However, combining evidence arising from RCTs and MR studies directly informs on the anticipated effects of vitamin D supplementation in the general population.

## 2. Type 2 diabetes

Since 2015, at least five well-powered MR studies have investigated the causal role of genetically determined 25(OH)D levels on risk of type 2 diabetes (T2D) and related traits. The earliest MR study [12], comprising several European populations of European descent, utilized four SNPs within or near genes related to 25(OH)D synthesis and metabolism (*DHCR7*-rs12785878, related to vitamin D synthesis; *CYP2R1*-rs10741657, the hepatic 25-hydroxylase; *GC*-rs2282679 involved in 25(OH)D transport; and *CYP24A1*-rs6013897 involved in catabolism) to infer 25(OH)D levels. These SNPs together explain 2.4% of the variance in 25(OH)D levels. Each SNP was assessed for an association with risk of T2D in a sample of 28,144 cases and 76,344 controls, and with glycemic traits (concentrations of fasting glucose, 2-h glucose at OGTT, fasting insulin, and HbA<sub>1c</sub>) among 46,368 individuals. These associations were then combined in an MR analysis to estimate the causal association of 25(OH)D concentration with T2D risk and with the glycemic traits. The MR effect (OR) for T2D was 1.01 (95% CI 0.75–1.36) per 25 nmol/L (equivalent to 1 standard deviation [SD]) lower 25(OH)D concentration. The MR-derived estimates for all four glycemic traits were not significant (all  $P > .25$ ). Therefore, it was concluded that association between genetically determined 25(OH)D concentration and T2D is unlikely to be causal.

Another MR study [46] investigated SNPs in the same four vitamin D genes in a metaanalysis of 10 studies (combining European and Chinese populations). The per allele effect across genetic scores on 25(OH)D levels was 2.87 nmol/L for the two synthesis SNPs (in *DHCR7* and *CYP2R1*) examined in 58,312 cases and 3.54 nmol/L for a four SNP score examined in 32,796 cases. Studying a nonlinear effect of genetically determined levels with a

cutoff of 25 nmol/L using the synthesis SNPs, indicated that a 25(OH)D concentration above this threshold was protective with an MR OR of 0.86 (95% CI 0.77–0.97) for T2D. An equivalent difference in 25(OH)D using a genetic score constructed from the four SNPs was not significantly associated with T2D (MR OR 0.92, 95% CI 0.84–1.01). These discordant results are difficult to interpret, but the absence of causal association based on the four SNP scores is notable, given that these SNPs explain a larger portion of the variance in 25(OH)D levels than the two synthesis SNPs alone.

In 2019, an umbrella MR paper [56] investigated associations of 25(OH)D levels and multiple traits in 339,256 individuals of White British origin from UK Biobank, among which T2D status. In this study, six SNPs were used as instrument to infer 25(OH)D levels, including the four previous SNPs and two newly identified SNPs in *SEC23A* and *AMDHD* (both genes do not have clear role in vitamin D synthesis and metabolism). These six SNPs together explain 5.3% of the variance in 25(OH)D levels. This MR analysis, with substantial study power (>80% power to detect an association with an OR >1.2 per SD increase of log-transformed 25(OH)D), did not support a causal association with T2D (MR OR 0.97, 95% CI 0.85 to 1.12 per 1SD increase in the log-transformed 25(OH)D level).

A two-sample MR study [55] on a larger population totaling 898,130 individuals of European ancestry (74,124 T2D cases and 824,006 controls) from the DIAGRAM consortium used SNPs in the same six vitamin D genes as the previous study, and a low-frequency variant of large effect on 25(OH)D level in *CYP2R1* (rs10741657). Using an IVW method, they demonstrated, per 1 SD increment of 25(OH)D levels, a protective MR OR for T2DM of 0.94 (95% CI 0.88–0.99). Results from the weighted median method and from the MR-Egger regression (both methods are sensitive to directional pleiotropy) were not significant.

Finally, a recent one-sample MR study [90] using up to 285 SNPs, all significantly associated with 25(OH)D levels, investigated the causal role of 25(OH)D in multiple outcomes in 417,580 White British individuals from UK Biobank. These SNPs explain nearly 13% of the variance in 25(OH)D levels. Using sensitivity analyses excluding SNPs with possible pleiotropic effects, and adjusting or not for BMI, this MR analysis failed to provide evidence for an unconfounded association between genetically lowered 25(OH)D levels and T2D (MR ORs 0.96, 95% CI 0.91 to 1.02 without adjustment for BMI; 0.98, 95% CI 0.93 to 1.03 with SNPs conditioned on BMI; and 1, 95% CI 0.94 to 1.05 when using BMI as a covariate). These results were similar to those of an MR study [66] using only 10 25(OH)D SNPs and including up to 80,983 T2D cases and 842,909 noncases. This study showed that a genetically predicted 1-SD increase in

25(OH)D was not significantly associated with T2D (MR OR 0.96, 95% CI 0.89–1.03).

In non-Europeans, an MR study in 16,135 Chinese individuals [62] used four SNPs in *DHCR7*, *CYP2R1*, *GC*, and *CYP24A1* and tested effects of 25(OH)D on T2D risk and glycemic traits. The MR-derived OR for risk of T2D (in a sample of 1565 cases and 10,655 controls) and prediabetes (among 3915 cases and 10,655 controls) was 0.99 (95% CI 0.94–1.03) and 0.98 (95% CI 0.95–1.02), respectively. The MR estimates for fasting plasma glucose and HbA<sub>1c</sub> were also not significant. The most recent MR study in Chinese participants [67] studied effects on T2D risk in 2393 individuals (361 cases) and demonstrated an OR of 1.10 (95% CI 1.02–1.45) for T2D when constructed from the two synthesis SNPs in *CYP2R1* and *DHCR7*, but no effect when using four SNPs comprising both synthesis and metabolism genes (*CYP2R1*, *DHCR7*, *GC*, and *CYP24A1*).

Overall, the aforementioned evidence converges to an absence of causal association between 25(OH)D levels and T2D or glycemic traits in Europeans and Asians.

### 3. Risk of cancers

A handful of MR studies have investigated the association between serum 25(OH)D concentration and the risk of cancer in individuals of European background. For start, the Ovarian Cancer Association (OCA) Consortium (10,065 cases, 21,654 controls) [18] reported a 27% increase in the risk of epithelial ovarian cancer risk per 20 nmol/L decrease in genetically determined 25(OH)D serum concentration (MR OR 1.27, 95% CI 1.06–1.51). The effect was stronger in high-grade serous epithelial ovarian cancer (MR OR 1.54, 95% CI 1.19–2.01). However, these findings were not fully corroborated by a follow-up study [26] comprising 4369 cases and 84,418 controls, reporting a nonsignificant MR OR of 1.12 (95% CI 0.86–1.47) per 25 nmol/L increase in genetically determined 25(OH)D levels. This discrepancy can be due to differences in power or to the quality of the genetic instrument (derived from 2346 participants in the first study [18], versus up to 38,000 individuals from a large-scale metaanalysis in the latter study [26]). The latter publication [26] also showed no evidence of association between genetically determined 25(OH)D concentrations and risk of colorectal (MR OR 0.92, 95% CI 0.76 to 1.10), breast (MR OR 1.05, 95% CI 0.89–1.24), prostate (MR OR 0.89 95% CI 0.77–1.02), lung (MR OR 1.03, 95% CI 0.87–1.23), pancreatic (MR OR 1.36, 95% CI 0.81–2.27), and cancer and neuroblastoma (MR OR 0.76, 95% CI 0.47–1.21). Similar findings were reported in another study [22] using five SNPs as instrumental variables mapping to the

*DHCR7*, *CYP2R1*, and *GC* genes in relation with total incident cancer (3985 cases, MR OR 1.10, 95% CI 0.96–1.25) and cancer subtypes such as breast (1560 cases, MR OR 1.14, 95% CI 0.92–1.41), colorectal (329 cases, MR OR 1.54, 95% CI 0.96–2.46), and lung (330 cases, MR OR 0.96, 95% CI 0.55–1.68) cancer in 23,294 women. The null effect on colorectal carcinoma was confirmed in a relatively large MR study (18,967 cases and 48,168 controls) using seven SNP mapping to *DHCR7*, *CYP2R1*, *GC*, *CYP24A1*, *SEC23A*, and *AMDHD1* [29]. Similarly, a large-scale MR study (122,977 breast cancer cases and 79,148 prostate cancer cases) did not show a causal effect of 25(OH)D concentrations on breast (MR OR 1.02, 95% CI 0.97–1.08) and prostate (MR OR 1.00, 95% CI 0.93–1.07) cancer risk [63]. 25(OH)D concentrations were also not associated with the risk of oral and oropharyngeal cancer [21] (5133 cases and 5984 controls) and esophageal adenocarcinoma (4112 cases and 17,159 controls) [45]. Moreover, the OR per 20 nmol/L increase in genetically estimated 25(OH)D concentration was 1.11 (95% CI 0.91–1.35) for nonmelanoma skin cancer (6167 cases and 23,326 controls) [31] and 0.94 (95% CI 0.87–1.05) for melanoma (12,874 cases and 23,203 controls) [59], indicating that vitamin D levels may not be causally associated with the risk of skin cancer. Genetically determined 25(OH)D was also not associated with increased glioma risk (MR OR 1.21, 95% CI 0.90–1.6) [33]. All aforementioned MR observations have been reevaluated and confirmed using a larger set of variants associated with 25(OH)D concentrations (up to 110 SNPs) [26,29,68,69,97]. Overall, the current MR studies support a potential protective effect of vitamin D on ovarian cancer but not for any other types such as breast, prostate, and colorectal cancer among others.

### 4. Risk of cardiovascular events

To date, six MR studies have investigated the effect of genetically determined 25(OH)D levels on cardiovascular events and related outcomes. A study using SNPs in the two vitamin D synthesis genes (*DHCR7* and *CYP2R1*) as instruments for 25(OH)D levels investigated the cardiovascular mortality rates in a population of 95,766 Europeans [17]. The study demonstrated that a decrease by 20 nmol/L in genetically determined 25(OH)D levels does not increase deaths from cardiovascular events (MR OR 0.77, 95% CI 0.55–1.08). Another MR study [14] on 89,995 Europeans (22,244 cases), using four vitamin D SNPs in *DHCR7*, *CYP2R1*, *GC*, and *CYP24A1*, also failed to provide evidence in favor of a causal association between 25(OH)D and coronary artery disease (MR OR 0.99, 95% CI 0.84 to 1.17, per 1-SD decrease in log-transformed 25(OH)D level).

An umbrella MR study using six vitamin D SNPs [56] (the four aforementioned SNPs, and two SNPs in *SEC23A*, and *AMDHD1*), and a substantially larger sample size (339,256 White British from UK Biobank, among which 28,337 had ischemic heart disease), showed a null association between 25(OH)D levels and ischemic heart disease (MR OR 1.02, 95% CI 0.92–1.14). An MR study on risk of ischemic stroke in 438,847 Europeans from the MEGASTROKE consortium [42], using the same six 25(OH)D-related SNPs corroborated this finding (MR OR 1.01, 95% CI 0.94–1.08). Contrarily, genetically determined lower 25(OH)D serum levels have been associated with the recurrence of ischemic vascular events in persons with prior ischemic stroke or MI [84] (MR OR 0.55, 95% CI 0.35–0.81 and MR OR 0.52, 95% CI 0.30–0.81, respectively). An one-sample umbrella MR study using a substantially larger number of 25(OH)D SNPs (242<sub>total</sub> or 232<sub>bmiadjusted</sub>) [90], explaining up to 13% of the variance in 25(OH)D levels, reported similar negative results to the studies mentioned before with an MR OR for coronary artery disease of 0.98 (95% CI 0.95–1.02) in a sample of 417,580 white British participants from the UK Biobank. Finally, using a combined Chinese and Danish population, totaling 205,923 individuals, an MR study [58] equally failed to provide evidence for a causal association between 25(OH)D and six cardiovascular traits, using two vitamin D synthesis SNPs (*DHCR7* and *CYP2R1*). Specifically, they demonstrated an MR OR of 1 for cardiovascular disease, myocardial infarction, stroke, ischemic stroke, intracerebral hemorrhage, and ischemic heart disease, with a tight 95% CI. Although the definition and type of cardiovascular events may differ among the above MR studies, and with a few exceptions, the null estimates are consistent.

## 5. Hypertension

The MR evidence for a causal effect of 25(OH)D levels on hypertension and systolic and diastolic blood pressure is consistent across five large studies, and overall does not support such effect. Specifically, an MR study [13] using as instruments two SNPs in the two vitamin D synthesis genes (*CYP2R1* and *DHCR7*) and drawn in a population of 146,581 Europeans with available measurements of systolic and diastolic blood pressure, and information on hypertension diagnosis, showed a marginal decrease in diastolic heart pressure 0.29 mm Hg per 10% increase in 25(OH)D levels. There was no significant effect on systolic heart pressure, and the MR OR for hypertension was 0.92 (95% CI 0.87–0.97). More recently, using six 25(OH)D-related SNPs (in *DHCR7*, *CYP2R1*, *GC*, *CYP24A1*, *SEC23A*, and *AMDHD1*), an umbrella MR study in 339,256 White British participants

of the UK Biobank studied effects of 25(OH)D on hypertension and systolic and diastolic blood pressure, among other outcomes. Similar to the previous study, they failed to show any evidence for a causal association between genetically determined 25(OH)D levels and all three outcomes (all *P*-values >0.20) [56]. Finally, using up to 252 SNPs (applying SNP-filtering for pleiotropy) as instruments for 25(OH)D levels, a one-sample umbrella MR study [90], showed a marginal effect of 25(OH)D levels on risk of hypertension (MR OR 0.97, 95% CI 0.94–1.0) in 417,580 White British from UK Biobank. After adjusting for BMI, this estimate was no longer significant.

MR findings drawn in non-Europeans are consistent with those reported in European populations. Specifically, in 2581 Korean adults, MR failed to demonstrate any causal effect of 25(OH)D levels (inferred by four SNPs in *DHCR7*, *CYP2R1*, *GC*, and *CYP24A1*) on systolic and diastolic blood pressure and risk of hypertension (all *P*-values >0.45) [52]. Using four SNPs in the same genes, an MR study on 10,655 Chinese adults [54] showed equally a null effect of genetically determined 25(OH)D on systolic and diastolic blood pressure (MR estimate –0.20, 95% CI –3.0 to 2.6, and 0.06, 95% CI –1.78 to 1.90, respectively, per 10 nmol/L increase in 25(OH)D level).

In conclusion, all the aforementioned evidence does not support a causal role of 25(OH)D in hypertension in Europeans and Asians.

## 6. Musculoskeletal outcomes

There is strong evidence from MR studies showing no causal effect of vitamin D on a variety of bone traits in both Europeans and non-Europeans. The largest study in Europeans [24] reported that a genetically predicted 1 SD increase in 25(OH)D was not associated with higher femoral neck bone mineral density (BMD) (MR estimate 0.02, 95% CI –0.03–0.07), lumbar spine BMD (MR estimate 0.02, 95% CI –0.04–0.08), or estimated BMD (MR estimate –0.03, 95% CI –0.05 to –0.01). Similar results were observed in relation with total body BMD (MR estimate 0.92, 95% CI 0.82–1.04) [25]. Both studies performed a variety of sensitivity analyses, assessing heterogeneity and pleiotropy, after which the main effects remained unchanged. A large MR study on 37,857 fracture cases and 227,116 controls also did not support a causal effect of 25(OH)D on fracture risk (MR OR 0.84, 95% CI 0.70–1.02) [47], although an umbrella MR study showed a possible effect on leg and femur fractures [91]. Interestingly, a pediatric study showed that haplotypes associating with low 25(OH)D were also associated with low pQCT parameters (BMD, cross-

sectional area, and cortical density) in 2-year-old children [50], indicating that vitamin D may be important in this age group. More evidence from MR in children is needed to make strong inference of causality.

An MR study [19] using four SNPs, *GC*, *DHCR7*, *NADSYN1*, *CYP2R1*, and *CYP24A1* as instruments also did not provide evidence for causal associations between serum 25(OH)D and either BMD or bone metabolism markers in 1824 postmenopausal Chinese women. Per unit increase in log-transformed 25(OH)D, the MR effect was  $-0.048$  (95% CI  $-0.158$  to  $0.062$ ) for lumbar spine BMD,  $-0.044$  (95% CI  $-0.120$  to  $0.032$ ) for femoral neck BMD,  $-0.041$  ( $-0.123$ ,  $0.041$ ) for total hip BMD,  $0.088$  (95% CI  $-0.034$ – $0.210$ ) for parathormone (PTH), and  $0.099$  (95% CI  $0.291$ – $0.093$ ) for the amino-terminal propeptide of type 1 procollagen (P1NP).

Genetically determined higher serum 25(OH)D levels had a positive effect on total (MR estimate  $0.042$ , 95% CI  $0.005$ – $0.079$ ), trunk (MR estimate  $0.045$ , 95% CI  $0.006$ ,  $0.084$ ), and arm (MR estimate  $0.04$ , 95% CI  $0.015$ ,  $0.073$ ) fat-free mass; but not with leg fat-free mass (right leg MR estimate  $0.03$ , 95% CI  $-0.021$ ,  $0.081$ ; left leg effect  $0.039$ , 95% CI  $-0.006$  to  $0.084$ ) [89]. However, comprehensive and well-powered MR studies are needed to disentangle the effect of genetically determined 25(OH)D levels with muscle outcomes and traits. No MR studies so far have examined the causal association between genetically determined 25(OH)D levels and risk of falls.

## 7. Lung function and respiratory conditions

To date, there are no MR studies that have examined the effect of vitamin D on chronic obstructive pulmonary disease and lung function. There are only few MR studies that have investigated the causal association between vitamin D and asthma. An MR study on a small pediatric cohort [20] (5080 controls and 1203 cases) created an allelic score from two SNPs located near *GC* and *CYP2R1* and reported no association between genetically determined 25(OH)D concentrations on asthma (MR OR  $1.00$ , 95% CI  $0.996$ – $1.004$  or severe asthma exacerbations (MR OR  $0.99$ , 95% CI  $0.90$ – $1.09$ ). The findings were later confirmed by a study with relatively large study settings [36] and reported an MR OR of  $1.03$  (95% CI  $0.90$ – $1.19$ , 146,761 controls and 25,109 cases) for asthma and  $0.95$  (95% CI  $0.69$ – $1.31$ , 15,008 controls and 7047 cases) for childhood-onset asthma per standard deviation decrease in log-transformed 25(OH)D. Overall, the current studies do not support a causal association between 25(OH)D and the risk of asthma.

## 8. Immune disorders

There have been several MR studies examining the effect of 25(OH)D on a variety of immunological diseases. Currently, there is strong evidence supporting causal association between genetically low 25(OH)D levels and increased risk of multiple sclerosis (MS). The initial MR study in 2015 [15] used SNPs in/near *GC*, *DHCR7*, *CYP2R1*, and *CYP24A1* to infer causality between 25(OH)D levels and MS in Europeans and reported a 2.0-fold increase in the odds of MS (95% CI  $1.7$ – $2.5$ ) per 1 SD decrease in log-transformed 25(OH)D level. Recently, the findings were replicated in a larger and more powerful study [48], which included six loci (*CYP2R1*, *DHCR7*, *CYP24A1*, *SEC23A*, and *AMDHD1*) associated with 25(OH)D levels and reported a 75% increase in odds of MS (95% CI  $1.23$ – $2.44$ ) per one unit decrease in the natural log-transformed vitamin D level. Importantly, the study reported evidence for possible reverse causation between vitamin D and MS. The aforementioned results were replicated in at least two more recent MR studies: the first study [88], using 138 25(OH)D SNPs, showed a protective effect (MR OR  $0.82$ , 95% CI  $0.69$ – $0.99$ ) in a population of 14,498 MS cases and 24,091 controls. The second study [91] used 143 SNPs in an umbrella MR analysis in the UK Biobank and showed an MR OR for MS of  $0.96$  (95% CI  $0.94$ – $0.98$ ).

MR data do not support any association between 25(OH)D levels and systemic lupus erythematosus (MR OR  $1.03$ , 95% CI  $0.82$ – $1.303$ ) or rheumatoid arthritis (MR OR  $1.03$ , 95% CI  $0.91$ – $1.16$ ) [37] using three SNPs mapping to/near *SSTR4*, *GC*, and *NADSYN1* as instruments. A similar effect on rheumatoid arthritis was reported by the UK Biobank using  $\sim 220$  vitamin D-associated SNPs as instrumental variables (MR OR  $1.01$ , 95% CI  $0.80$ – $1.27$ ) [90]. A null effect was also reported for risk of juvenile idiopathic arthritis [70] in a sample of 14,872 cases and 12,501 controls. Similar results were obtained for risk of ankylosing spondylitis [71]. Recently, an MR study on 23,877 cases for knee osteoarthritis and 17,571 cases for hip osteoarthritis and using 6 25(OH)D SNPs, found no effect of 25(OH)D for any of the two outcomes [72].

Vitamin D levels have also been shown not to be causally associated with Crohn's disease and ulcerative colitis. Per 10 nmol/L higher genetically determined 25(OH)D levels, the ORs were  $0.88$  (95% CI  $0.64$ – $1.21$ ) for Crohn's disease and  $1.04$  (95% CI  $0.82$ – $1.32$ ) for ulcerative colitis [39]. Similarly, no effect on ulcerative colitis was reported by the UK Biobank using  $\sim 270$  vitamin D-associated SNPs as instrumental variables (MR OR  $0.99$ , 95% CI  $0.79$ – $1.26$ ) [90]. This one-sample MR study in UK Biobank did support a causal role of

vitamin D on allergic rhinitis (MR OR 1.04, 95% CI 1.01–1.10). Also, MR failed to show a causal effect on genetically estimated 25(OH)D on atopic dermatitis (MR OR 1.12, 95% CI 0.92–1.37) [36], while a more recent study showed null effects on allergic and nonallergic rhinitis and risk of allergic sensitization [73].

The only available MR studying the effects of vitamin D on type 1 diabetes [74] used 69 common 25(OH)D SNPs and did not show a significant effect of vitamin D levels in a cohort of 9358 cases and 15,705 controls of European ancestry (MR OR 1.09, 95% CI 0.86–1.40, per 1-SD decrease in standardized log-transformed 25(OH)D). Finally, a metaanalysis of MR studies on a total of 2214 cases and 5695 controls from Asian and European background found a significant effect of 25(OH)D levels (MR OR 3.96, 95% CI 1.72–9.13) on risk of Behcet's disease [75].

## 9. Pregnancy-related outcomes

To date, only one MR study [38] has examined the causal effect of 25(OH)D serum levels on pregnancy-related hypertensive disorders such as gestational hypertension and preeclampsia, using vitamin D synthesis and metabolism SNPs. In total, the study included 7389 women in a one-sample MR analysis (751 with gestational hypertension and 135 with preeclampsia), and 3388 preeclampsia cases and 6059 controls in a two-sample MR analysis. There was no strong evidence to support a causal effect of vitamin D status on gestational hypertension (MR OR 0.90, 95% CI 0.78–1.03) or preeclampsia (MR OR 0.98, 95% CI 0.89–1.07). Another MR study did not find any association between the maternal vitamin D status and the first child's birthweight in UK Biobank (MR estimate [difference in mean birth weight] –0.03 g, 95% CI –2.48 to 2.42 g per 10% higher maternal 25(OH)D) [60].

## 10. Neuropsychiatric outcomes

MR has been used to study the role of vitamin D on several neuropsychiatric outcomes, such as depression, attention-deficit/hyperactivity disorder (ADHD), and Alzheimer's disease (AD). For instance, it has been reported that genetically increased 25(OH)D levels are associated with reduced AD risk [16,40,51]. However, a recent large-scale MR study using 138 SNPs failed to corroborate the beneficial effect of 25(OH)D levels on AD risk [97]. Further, MR showed no clear support that genetically determined 25(OH)D levels are causally associated with risk of Parkinson's disease (MR OR 0.98,

95% CI 0.93–1.04) [34] nor of depression (MR OR 0.97, 95% CI 0.90–1.05) [64]. This corroborates the findings from previous MR studies [41,57,61]. Similarly, MR did not support a causal relationship between 25(OH)D levels in studies investigating other forms, such as treatment-resistant depression in 1891 cases (MR OR 1.01, 95% CI 0.78–1.31) or atypical depression in 2101 cases (MR OR 1.04, 95% CI 0.80–1.36) [80]. In contrast, using a bidirectional MR analysis, genetic predisposition to depression was associated with lower 25(OH)D concentrations [64]. There is also little evidence for a causal effect of 25(OH)D on fatigue (MR OR 1.05, 95% CI 0.87–1.27, per 1-SD decrease in log-transformed 25(OH)D) [32]. Furthermore, it has been shown that participants carrying more vitamin D-increasing variants have reduced likelihood of incident delirium diagnosis (HR 0.80, 95% CI 0.73–0.87, per 1-SD increase in genetically determined vitamin D) [78]. MR also suggests no evidence for a causal effect of 25(OH)D on ADHD risk [79] or amyotrophic lateral sclerosis [53].

## 11. COVID-19

Given the recent advent of observational studies suggesting that vitamin D supplementation could modify the risk of COVID-19-related outcomes, MR studies were launched to assess the causal role of 25(OH)D levels on COVID-19 susceptibility and disease severity. Using data from 11,181 cases and 116,456 controls from the Host Genetics Initiative, and 17 vitamin D SNPs explaining 2.5% of the variance in 25(OH)D levels, this study [83] did not show any evidence for association between genetically decreased 25(OH)D and COVID-19 outcomes (MR OR 1.04, 95% CI 0.91–1.03, for COVID-19 infection, and MR OR 0.79, 95% CI 0.58–1.08, for severe COVID-19 infection). These results were confirmed by a separate MR study [82] using 81 25(OH)D SNPs explaining 4.3% of the variance in 25(OH)D levels, which also showed no impact of genetically determined 25(OH)D levels on risk of COVID-19-related hospitalization (MR OR 0.95, 95% CI 0.84–1.08 for COVID-19 risk, MR OR 1.09; 95% CI 0.89–1.33 for hospitalization, and MR OR 0.97, 95% CI 0.77–1.22 for severe COVID-19 infection).

## 12. Mortality risk and aging

In a large-scale study on mortality risk (comprising 10,349 deaths in 95,766 participants) [98], genetic variants in the vitamin D synthesis pathway mapping to *DHCR7* and *CYP2R1* were used as instruments to infer

25(OH)D levels. The MR OR for a genetically determined 20 nmol/L lower 25(OH)D concentration was 1.30 (95% CI 1.05–1.61) for all-cause mortality, 0.77 (95% CI 0.55–1.08) for cardiovascular mortality, 1.43 (95% CI 1.02–1.99) for cancer mortality, and 1.44 (95% CI 1.01–2.04) for other mortality. Similar nonsignificant effect sizes were reported [28] per 20 nmol/L decrease in genetically determined 25(OH)D levels, specifically 1.32 (95% CI 0.80–2.24) for all-cause mortality in a combined sample from three European cohort studies (10,501 participants and 4003 deaths). This study may have been underpowered to detect existing causal associations with mortality. In addition, no causal effect (MR OR 1.09, 95% CI 0.79–1.50) was reported [56] using six independent SNPs in *GC*, *NADSYN1/DHCR7*, *CYP2R1*, *CYP24A1*, *AMDHD1*, and *SEC23A*. This study reported having 85% power to detect an OR of 1.2; thus, it may have not been powered to detect possible smaller effects. Finally, no significant association was found between 25(OH)D levels and cancer mortality (MR OR 0.97, 95% CI 0.84–1.11, in 6998 deaths) [27]. Importantly, recent MR studies have demonstrated a nonlinear causal effect on all-cause mortality (discussed in the following). MR also showed a null effect on telomer shortening (MR estimate  $-0.10$ , 95% CI  $-0.27$  to  $0.06$ ), often considering proxy of human aging [49].

### 13. Other outcomes

Several other disease-related outcomes have been subject of scrutiny for a relationship with vitamin D levels using the MR approach. For every 1 SD increase in genetically determined 25(OH)D, the combined MR OR of NAFLD was 0.78 (95% CI 0.69–0.89). Genetically predicted higher levels of 25(OH)D showed a suggestive association with aspartate aminotransferase levels (MR estimate  $-0.17$ , 95% CI  $-0.36$  to  $0.01$ ) [87]. Genetic predisposition to a 1 SD higher 25(OH)D level was associated with increased serum calcium levels (MR estimate 0.014, 95% CI 0.010–0.018) and increased risk of kidney stones (MR OR 1.47, 95% CI 1.22–1.77) [85]. Furthermore, MR reported a negative causal effect of log-transformed 25(OH)D on log-transformed eGFR (MR estimate  $-0.013$ , 95% CI  $-0.002$  to  $-0.005$ ) [35]. MR did not provide evidence of a causal effect of vitamin D on concentrations of C-reactive protein (MR estimate  $-0.001$ , 95% CI  $-0.007$  to  $0.005$ ),  $\alpha$ 1-acid glycoprotein (MR estimate  $-0.001$ , 95% CI  $-0.008$  to  $0.006$ ), and soluble intercellular adhesion molecule 1 (MR estimate  $-0.002$ , 95% CI  $-0.009$  to  $0.005$ ) [65]; all considered relevant inflammatory biomarkers. MR showed a suggestive association between 1-SD increase in genetically determined 25(OH)D and lower levels of cholesterol, lipoprotein particles, and phospholipids within

very-small very-low-density lipoprotein (VLDL) and intermediate-density lipoprotein (IDL) [92]. Per 1-SD increase in genetically determined 25(OH)D, there was 0.12 units decrease in total testosterone in 4254 Chinese men (95% CI, 0.02–0.22) [23]. On the other hand, a null MR effect of 25(OH)D was shown on circulating insulin-like growth factor-binding protein 3 (IGFBP-3) levels [43].

A potential causal association of serum 25(OH)D with number of remaining natural permanent teeth (MR estimate 0.085, 95% CI 0.019–0.150) was reported [86] but not with dental caries or periodontitis. Two additional MR studies have also reported a null effect on caries [77] and periodontitis risk [81]. Genetically determined 25(OH)D levels are reported to not have an effect on refractive error (MR estimate  $-0.02$ , 95% CI  $-0.09$  to  $0.04$  diopters per 10 nmol/L increase in 25(OH)D concentration in Caucasians and 0.01 95% CI  $-0.17$  to  $0.19$  diopters per 10 nmol/L increase in Asians) [30]. Also, MR showed no causal association between 25(OH)D and features of skin aging [44].

### 14. Nonlinear MR studies

Taking advantage of the availability of data on 25(OH)D levels and a large spectrum of phenotypes in UKBB and other large-scale genotyped cohorts, the MR design was recently adapted to study nonlinear effects. To do this, one-sample MR studies have been undertaken in strata of the studied populations, specifically in individuals presenting deficient, insufficient, sufficient, and adequate 25(OH)D levels ( $<25$  nmol/L, 25–50 nmol/L, 50–75 nmol/L, and  $>75$  nmol/L, respectively). A stratified MR study [99] investigated the effect of 25(OH)D on cardiovascular disease (CVD), ischemic stroke, and all-cause mortality using 71 SNPs, explaining up to 4.7% of the variance in 25(OH)D. The study population comprised 386,406 middle-aged cases with CVD, 18,166 people who had a stroke, and 27,885 people who died. MR analyses showed in individuals with vitamin D deficiency an inverse association with all-cause mortality (OR per 10 nmol/L increase in genetically predicted 25(OH)D concentration 0.69 (95% CI 0.59–0.80) and nonsignificant inverse associations with stroke (MR OR 0.85, 95% CI 0.70–1.02) and CVD (MR OR 0.89, 95% CI 0.76–1.04). Another nonlinear MR study [100] used 35 SNPs explaining 2.8% of the variance in 25(OH)D levels in a population of 44,591 CVD cases and 251,269 controls of the UKBB. They showed an L-shaped association between genetically predicted serum 25(OH)D and CVD risk ( $P = .007$ ), and a similar association for systolic blood pressure ( $P = .03$ ) and a trend for diastolic blood pressure ( $P = .07$ ).

## 15. Conclusion

Improved understanding of the genetic determinants of 25(OH)D has helped reassess the role of vitamin D in the etiology of complex traits and diseases through MR. Taken together, the evidence from over 100 available vitamin D MR studies does not support a causal role for the vast majority of studied health outcomes. Nonetheless, in the few cases where the evidence from MR supported causality of vitamin D, such as in the example of MS, these findings have important clinical implications. For instance, recent clinical care guidelines published by the MS Society of Canada recommend the use of vitamin D in preventing multiple sclerosis in those at increased risk [101]. Early MR studies used as instruments for 25(OH)D serum levels SNPs within the four genes related to 25(OH)D synthesis and metabolism (*DHCR7*, *CYP2R1*, *GC*, and *CYP24A1*), which together explained 2.4% of the variance in 25(OH)D levels [102]. Subsequent MR studies combined the aforementioned four SNPs with two additional SNPs mapping to *SEC23A* and *AMDHD1* (both genes without clear role in the vitamin D metabolic pathway), explaining together ~5.3% of the variance of 25(OH)D levels. The recent identification of over 150 25(OH)D-associated genetic variants, which explain a significantly larger portion of the variance in 25(OH)D levels (~10.5%) [90], has allowed a deeper understanding of the genetic determinants contributing to variation in circulating 25(OH)D levels and has enabled an improved instrumentation of vitamin D in MR studies.

The MR results corroborate with the data generated by recent megatrials of vitamin D supplementation [7–10] of largely vitamin D-sufficient adults, demonstrating that increasing serum 25(OH)D concentration into the high normal range (based on the Institute of Medicine and most recent guidelines in the range of 50–125 nmol/L or 20–50 ng/mL) does not generate benefits for global health or major diseases such as cancer, cardiovascular events, T2D, or fractures. Therefore, there is no reason at present to recommend vitamin D supplementation in already vitamin D replete subjects. This contention does not contradict the causal link between severe vitamin D deficiency and rickets and the need to correct (severe) deficiency at any age. In this line, findings from recent nonlinear MR studies support the need to correct vitamin D deficiency to prevent CVD and all-cause mortality, which is in line with previous evidence from RCTs. Further, evidence from nonlinear MR studies can elucidate causal associations of 25(OH)D levels with diseases and traits in individuals with 25(OH)D in the extremes of the normal distribution. These dose-dependent effects of 25(OH)D levels need to be also evaluated in well-designed RCTs.

The available evidence from vitamin D MR studies is largely concordant with that from RCTs. While these findings advocate correction of vitamin D deficiency, they do not argue in favor of systematically recommending vitamin D supplementation in replete individuals for a wide range of common diseases. With the emergence of large-scale GWAS on densely phenotyped biobanks, we anticipate that more powerful vitamin D MR studies will be published, utilizing optimized sets of genetic instruments, revisiting previously studied diseases, investigating new disease outcomes, and assessing nonlinear effects, to further aid causal effect estimation.

## 16. Summary points

- Over 100 MR studies have evaluated the consequences of lifelong genetically determined serum levels of 25(OH)D on various outcomes, and most studies have observed null effects.
- A notable exception are four independent MR studies showing a higher risk of multiple sclerosis in subjects with genetically lowered 25(OH)D.
- MR studies evaluating nonlinear effects have shown evidence for causal effects of low serum 25(OH)D (<50 nmol/L) on cardiovascular disease and all-cause mortality.
- Indiscriminate vitamin D replacement in the general population is unlikely to be helpful, except for the prevention of multiple sclerosis.
- Vitamin D replacement is likely beneficial for those with established vitamin D deficiency.

# Growth plate histology, bone histomorphometry, and radiologic features of nutritional rickets and osteomalacia

*Suma Uday<sup>1</sup> and Wolfgang Högler<sup>1,2</sup>*

<sup>1</sup>Institute of Metabolism and Systems Research, University of Birmingham and Birmingham Women's and Children's Hospital, Birmingham, United Kingdom <sup>2</sup>Johannes Kepler University, Linz, Austria

## OBJECTIVES

- Review the terminologies related to bone formation and mineralization.
- Understand the normal anatomy and the pathophysiology of rickets at the growth plate.
- Review the clinical and radiological features of rickets and osteomalacia.
- Review the differentiating classic radiological features of various forms of calcipenic and phosphopenic rickets.
- Review the histomorphometric features and bone mineralization density distribution curve on backscattered electron imaging in osteomalacia.
- Review the utility of other imaging modalities such as MRI and DXA scans in the diagnosis of hypomineralization disorders.

## 1. Introduction

Rickets results from defective mineralization of the growth plate and is seen in growing children. Osteomalacia, on the other hand, results from reduced mineralization of the preformed osteoid and can be seen in both adults and children. Rickets and osteomalacia can result

from lack of minerals (calcium and/or phosphate), mineral suppliers [calcitriol or 1,25 dihydroxyvitamin D (1,25(OH)<sub>2</sub>D)], or facilitators of mineralization [such as alkaline phosphatase (ALP)]. Several genetic causes of rickets and osteomalacia have been described; nonetheless, nutritional deficiencies in dietary calcium and/or vitamin D remain the leading causes worldwide [1,2]. The main source of vitamin D is cutaneous synthesis following skin exposure to ultraviolet B (UVB) rays in sunlight. Therefore, vitamin D deficiency (low serum 25-hydroxyvitamin D, 25(OH)D) is more commonly seen in high-latitude countries and predominantly in dark-skinned populations or in individuals adapting culturally covered clothing. The main source of calcium, however, is diet, and therefore, calcium deficiency is most commonly seen along with other nutritional deficiencies and predominates in the undernourished populations of low- to middle-income countries [3].

Rickets is a radiological diagnosis reflecting the histopathological changes of defective mineralization at the growth plate and adjacent metaphysis of long bones. Osteomalacia is not a radiological diagnosis but diagnosed on histomorphometry of bone biopsy, and reflects defective mineralization of the preformed osteoid. Both conditions, however, have typical clinical and biochemical features that aid in diagnosis. Since calcium and vitamin D deficiency are widespread micronutrient deficiencies, with serious health consequences, they represent a major global public health concern and require simple and cost-effective prevention strategies.

## 2. Terminology related to bone formation and mineralization

The terminologies relating to bone formation and mineralization are detailed in [Table 62.1](#).

**TABLE 62.1** Terminology relating to bone formation and mineralization.

Terminology	Clarification
Bone formation	Describes the process of synthesis of extracellular organic osteoid followed by its mineralization.
Ossification	Relates to the two major modes of bone development [4]: - <b>Endochondral ossification</b> seen in long bones (e.g., femur) where cartilage is replaced by bone tissue (discussed in detail later). - <b>Intramembranous ossification</b> seen in flat bones (e.g., skull). In intramembranous ossification, mesenchymal cells differentiate directly into osteoblasts, which in turn synthesize bone matrix. Unlike cartilage, bone is incapable of internal expansion, and therefore, the growth of bones formed by intramembranous ossification must occur through surface apposition.
Mineralization	Relates to the integration of hydroxyapatite [ $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ ] into osteoid.
Calcification or pathological mineralization	Deposition of calcium phosphate crystals in extraskeletal tissues (kidneys, skin, arteries, muscle, brain, tumors) [5].
Bone modeling	Process where bones are shaped or reshaped by the independent action of osteoblast and osteoclasts. Bone modeling defines skeletal development and growth but continues throughout life [6].
Bone remodeling	Process where osteoclasts and osteoblasts work sequentially in the same bone remodeling unit. The human skeleton is renewed by remodeling throughout life [6].
Rickets	Defective mineralization of the growth plate cartilage and adjacent primary and secondary spongiosa in the metaphysis (“new bone”).
Osteomalacia	Defective mineralization of newly formed osteoid in existing bone during remodeling (“old bone”).
Osteoporosis	Reduced bone mass and structural quality. It is not associated with reduced mineralization of bone tissue. Osteoporosis occurs when bone resorption exceeds bone formation (adults and children) or from reduced bone mass accrual (children).

## 3. The growth plate

The growth plate, wedged between the metaphysis and the epiphysis of long bones, is the key player in promoting long bone growth in children. Endochondral bone formation is the fundamental mechanism of bone growth. During endochondral ossification, the growth plate undergoes morphogenesis, and cartilage is replaced by bone. The process of ossification begins with the condensation of undifferentiated mesenchymal cells [7]. The cellular components of this condensation differentiate into chondrocytes that lay down the cartilage matrix, which is eventually replaced by bone [7]. The growth plate therefore is predominantly composed of cartilage and chondrocytes, which are arranged in distinctive layers. The three principal chondrocyte zones in the growth plate that contribute to longitudinal growth in the postnatal period are the resting, proliferative, and hypertrophic zones ([Fig. 62.1](#)).

The resting zone, adjacent to the epiphyseal bone, maintains the integrity of the growth plate structure, particularly by expressing parathyroid hormone related protein (PTHrP) [8]. The resting zone contains round chondrocytes embedded within the cartilaginous matrix, and as the cells begin to divide, the proliferative zone is formed [8]. The chondrocytes in the proliferative zone are arranged in columns parallel to the long axis of the bone, and the round proliferating chondrocytes become flattened as they are packed into multicellular columns. The proliferative chondrocytes farthest from the resting zone stop replicating and enlarge in size significantly to become hypertrophic chondrocytes [9]. The cells in the transition zone from proliferative to hypertrophic are also recognized as the “prehypertrophic” chondrocytes. The rate at which proliferating chondrocytes undergo hypertrophy determines bone elongation [10] with enlargement of the hypertrophic chondrocytes being the major contributing factor regulating the growth rate in endochondral bones. This metric is largely responsible for the variations in skeletal growth rates among different endochondral bones within an individual [11]. The hypertrophic chondrocytes produce a matrix rich in collagen X as well as angiogenic factors such as vascular endothelial growth factor (VEGF) [12] that attract blood vessels and bone cells. Hypertrophic chondrocytes express the molecular signals that direct mineralization of the surrounding matrix, such as the Indian hedgehog (Ihh). The terminally differentiated chondrocytes mineralize the cartilage matrix to form the zone of provisional calcification. The hypertrophic chondrocytes undergo apoptosis or differentiate into osteoblasts to form a bony matrix known as the primary spongiosa, which is the future site of trabecular bone [13].

**FIGURE 62.1** Normal human growth plate at the rib costochondral junction. Illustrates H&E stained ( $\times 4$  magnification) growth plate histology demonstrating normal growth plate with distinct chondrocyte zones (resting, proliferative, and hypertrophic) and spongiosa (primary and secondary).

The calcified cartilage matrix produced in the growth plate provides the template for the production of primary spongiosa (primary trabeculae). The osteoclasts (bone resorbing cells) remove cartilage matrix, and osteoblasts use the remnants of cartilage matrix as a scaffold for the deposition of bone matrix, thereby replacing the calcified cartilage with new (or secondary) trabecular bone resulting in remodeling into mature secondary spongiosa. Thus, during growth, there is a dynamic transformation of growth plate cartilage into new trabecular bone wherein growth plate matrix structure and bone trabecular structure are intimately associated having separate but complementary functions in achieving overall skeletal development. Overall, bone growth and development is tightly regulated by both systemic factors and locally secreted factors, which act on receptors to effect intracellular signaling and activation of chondrocyte-selective transcription factors, which are discussed in detail elsewhere [7,11,14].

### 3.1 The growth plate in rickets

The basic pathology underlying both phosphopenic and calcipenic (secondary hyperparathyroidism leading to renal phosphate wasting and subsequent hypophosphatemia) forms of rickets is the lack of phosphate at the growth plate [15]. Phosphate is essential for apoptosis of the hypertrophic chondrocytes and the mineralization that follows. Phosphate-regulated apoptosis of hypertrophic chondrocytes is activated via the caspase-9-mediated mitochondrial pathway [16]. Lack of apoptosis leads to accumulation of

hypertrophic chondrocytes, which leads to an expansion of the hypertrophic zone as the chondrocytes, previously arranged in columns, become disarrayed. Mice models with varying etiologies of low phosphate such as vitamin D receptor mutation, diet-induced hypophosphatemia/hypercalcemia (with suppressed parathyroid hormone), and hypophosphatemia secondary to mutations in the PHEX (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) gene (with normal calcium and parathyroid hormone levels, but inappropriately low 1,25-dihydroxyvitamin D levels) demonstrate changes of rickets at the growth plate [16]. Calcium-sensing receptor knockout mice also exhibit classical rachitic growth plates secondary to hyperparathyroidism (due to impaired parathyroid calcium sensing which leads to hypophosphatemia) supporting the hypothesis that phosphate is a key regulator of chondrocyte apoptosis [17]. Similarly, vitamin D receptor (VDR) null mice demonstrate rickets at growth plate and skeletal demineralization due to impaired intestinal calcium absorption and the resultant secondary hyperparathyroidism and hypophosphatemia [18]. The skeletal phenotype of the VDR null mice is reversed with introduction of a rescue diet enriched with calcium, phosphorus, and lactose indicating the rachitic changes are a direct result of deficient mineral supply at the growth plate, and not a direct effect of vitamin D [18].

The histological changes of rickets at the growth plate include [19] expansion and disarray of the hypertrophic zone due to accumulation of hypertrophic chondrocytes, lack of clear distinction between the various growth plate zones and fading of the zone of provisional

calcification, penetrating blood vessels in the hypertrophic chondrocyte cartilage zone, and tongue-like projections of cartilage extending into the primary spongiosa (Fig. 62.2A). The expansion of the hypertrophic zone leads to a bulbous appearance of the growth plate histologically (Fig. 62.2B).

In severe cases of rickets, the enlarged hypertrophied chondrocyte layer contributes to the clinical appearance of swollen joints at the wrist and/or ankle (Fig. 62.3A) and the corresponding radiological appearance of the widened metaphyses (Fig. 62.3B). Detailed radiological features of rickets are discussed in the radiology section. Bulbous expansion of the costochondral junction manifests as rachitic rosary or beaded ribs (Fig. 62.4).

#### 4. Mineralization

Bone is mineralized connective tissue composed of 50%–70% mineral with the most abundant minerals being calcium and phosphorus, present in the form of hydroxyapatite crystals  $[\text{Ca}_{10}(\text{PO}_4)_6\text{OH}_2]$  [4]. The mineralization process therefore requires adequate substrates, which are supplied by  $1,25(\text{OH})_2\text{D}$  through intestinal absorption. Additionally, tissue-nonspecific alkaline phosphatase (TNSALP) also plays a crucial role in the formation of hydroxyapatite crystals, and reduced activity leads to hypomineralization as seen in hypophosphatasia [20].

Several theories for the mechanism of initiation and regulation of cell-mediated mineralization have been proposed [21]. While it is not entirely clear as to what initiates mineralization, it is, however, well recognized that matrix vesicles (MVs) protruding from osteoblasts play an important role [22]. The first step in mineralization is the formation of hydroxyapatite in MVs of mature chondrocytes and osteoblasts [23]. In brief, during phase I, there is increased activity of the MV phosphatases (including ALP, adenosine triphosphatase, pyrophosphatase, and PHOSPHO1), which generate and transport phosphate, as well as calcium-binding compounds such as the annexin family and phosphatidylserine [24]. Calcium and phosphate are attracted into the MVs by these compounds, until the threshold for their precipitation is reached [22]. In phase II, the hydroxyapatite crystals penetrate the MV membrane and are elongated into the extracellular space [22], which requires appropriate concentrations of calcium and phosphate outside the MVs. TNSALP hydrolyses inorganic pyrophosphate (PPi), an inhibitor of hydroxyapatite formation, to inorganic phosphorus (Pi), thereby facilitating hydroxyapatite crystal formation [25]. The ratio of PPi to Pi is considered critical in the promotion or restriction of mineral in physiological tissues [23]. TNSALP, encoded by the *ALPL* gene, is found in abundance on the surface of MVs [26].

**FIGURE 62.2A** Changes of severe rickets on growth plate histology. Illustrates H&E stained ( $\times 4$  magnification) growth plate histology demonstrating significant histological changes of rickets. Arrow demonstrates the increased height of the hypertrophic zone and 1 = expansion of the hypertrophic zone, 2 = disarrayed hypertrophic chondrocytes, 3 = loss of distinction between hypertrophic and proliferative zones, 4 = blood vessels penetrating the chondrocytes, 5 = tongues of cartilage extending into primary spongiosa.

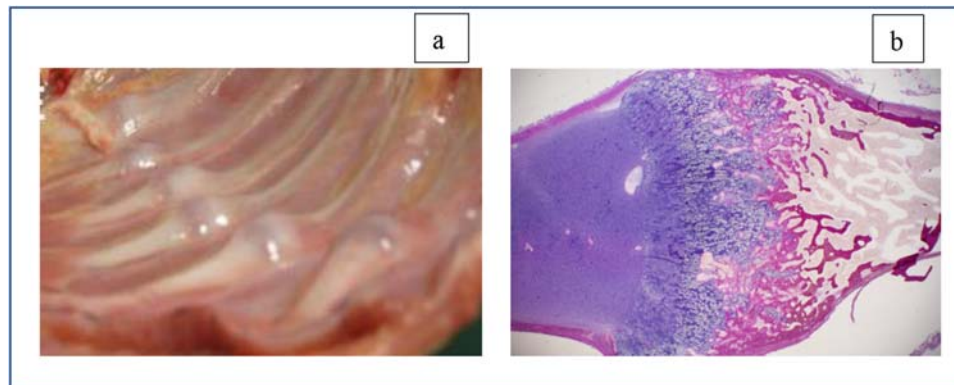

**FIGURE 62.2B** Changes of severe rickets on qualitative growth plate histology demonstrating bulbous expansion of the costochondral junction. Illustrates H&E stained ( $\times 1$  magnification) growth plate histology demonstrating significant histological changes of rickets. Arrow demonstrates height of the hypertrophic zone and 1 = expansion of the hypertrophic zone, 2 = disarrayed hypertrophic chondrocytes, 3 = loss of distinction between hypertrophic and proliferative zones, 4 = blood vessels penetrating the chondrocytes, 5 = tongues of cartilage extending into primary spongiosa, and 6 = bulbous expansion of the costochondral junction.

**FIGURE 62.3** (A) demonstrates swollen wrist joint in a 3.5-year-old child with severe nutritional rickets who presented with regression of motor development milestones (adjusted calcium 1.63 mmol/L, phosphate 0.7 mmol/L, ALP 1776 IU/L, 25 hydroxyvitamin D < 7.5 nmol/L, and parathyroid hormone 159 pmol/L (reference range 1.6–7.5)). (B) Illustrates the corresponding radiograph demonstrating widening of the metaphyses.

**FIGURE 62.4** (A) demonstrates rachitic rosary at postmortem examination in a 6-month-old child with severe nutritional rickets (adjusted calcium 1.6 mmol/L, ALP 802 IU/L, 25 hydroxy vitamin D < 15 nmol/L, parathyroid hormone 167 ng/L (reference range 12–29)) who presented in cardiac arrest due to hypocalcemic dilated cardiomyopathy. (B) Illustrates the corresponding histological section ( $\times 1$  magnification) of the seventh rib (Elastica van Gieson staining) demonstrating expansion and disarray of the hypertrophic zone.

## 5. Bone histomorphometry in osteomalacia

Histomorphometry is the quantitative evaluation of bone tissue including both the activity of bone cells and the amount and distribution of bone tissue. Histomorphometry enables the assessment of bone structure and the dynamics of bone modeling and remodeling through the administration of time-spaced two oral doses of tetracycline derivative prebiopsy. Osteomalacia is a histological diagnosis and is usually accompanied by typical biochemical derangements of serum ALP, calcium, and/or phosphate. However, it can sometimes exist in the absence of these biochemical abnormalities [27].

In osteomalacia, old bone resorbed during remodeling is replaced by unmineralized bone matrix (or osteoid tissue). Histological differentiation of osteomalacia from osteoporosis and osteitis fibrosa was first made by the

German pathologist Pommer in the late 19th century, which was subsequently elaborated by Parfitt based on the current concepts of bone remodeling [28]. Tetracyclines bind to newly calcified bone, which fluoresces under UV light. This characteristic is used to assess bone formation after giving oral tetracycline on two occasions (double labeling) before obtaining an iliac-crest biopsy. Based on tetracycline-labeled histomorphometry studies, Parfitt classified hypovitaminosis D osteopathy (HVO) into three stages [28].

- HVOi: The earliest stage of HVO where there is osteoid accumulation, before the emergence of a significant mineralization defect, because of increased frequency of remodeling activation and bone turnover due to secondary hyperparathyroidism. This state is also referred to as preosteomalacia.

- HVOii: The stage of defective mineralization where there is some retention of tetracycline double labels.
- HVOiii: The advanced stage of defective mineralization where tetracycline labels are not retained.

HVOi is characterized by an increase mainly in osteoid surface with a slight increase in osteoid thickness (usually  $<12.5\ \mu\text{m}$ ) [29]. In individuals with vitamin D deficiency, there is a hyperbolic relationship between osteoid surface and osteoid thickness, meaning that osteoid surface increasing first, and osteoid thicknesses increasing only when osteoid surface exceeds  $>70\%$  of the total bone surface [29]. Thereafter, any further increase in osteoid surface is accompanied by a substantial increase in osteoid thickness and osteoid volume. Additionally, a mineralization lag time, an index of the time interval between matrix apposition and its subsequent mineralization, of  $>100$  days separates patients with and without osteomalacia [29]. Histologic osteomalacia in adults is generally defined by a combination of osteoid thickness  $>12.5\ \mu\text{m}$  and a mineralization lag time of  $>100$  days [29]. Mineral apposition rate (MAR) can also be reduced in osteomalacia, but it is not specific to osteomalacia. Cortical thinning and bone marrow fibrosis occurring as a consequence of secondary hyperparathyroidism are additional features of vitamin D deficiency osteomalacia.

While the causes and histomorphometric features of osteomalacia are similar between adults and children, there is no specific definition of osteomalacia in children. There are no histomorphometry reference data from children under 1.5 years of age. In children aged 1.5–22.9 years ( $n = 58$ ), reference histomorphometry parameters are reported to be dynamic with osteoid surface relative to bone surface (OS/BS) and osteoid volume relative to bone volume (OV/BV) being naturally higher in the younger age groups demonstrating a steady decrease with age similar to the MAR [30]. The osteoid thickness,

however, is reported to be stable with age [30]. Fig. 62.5 illustrates Goldner's Trichrome stained iliac bone section of an infant who died of dilated cardiomyopathy and heart failure due to severe vitamin D deficiency [31]. Significant osteomalacia (Fig. 62.5) is noted with increased osteoid thickness ( $23.2\ \mu\text{m}$  [reference  $6.4 \pm 1.4$ ]), OS/BS ( $76.3\%$  [reference  $24.9 \pm 10$ ]), and OV/BV ( $40.5\%$  [reference  $2.4 \pm 1.22$ ]) when compared with normative data from older children (Fig. 62.5) [30].

A study of bone histomorphometry in Black African adolescents with dietary calcium deficiency ( $n = 26$ ) demonstrated an inverse correlation between serum calcium levels and eroded mineralized surface, osteoid surface, osteoid thickness, mineralization lag time, and  $1,25(\text{OH})_2\text{D}$  [32]. The cortical bone in calcium deficiency also displays features of hyperosteoridosis, and increased erosion and porosis secondary to hyperparathyroidism [33]. Children with calcium deficiency are reported to display osteomalacia even in the absence of radiological signs of rickets; however, most of these were adolescents where signs of rickets may not be evident due to closure of the growth plate [33]. Osteomalacia solely due to calcium deficiency in adults has not been assessed or reported to date [29].

In hypophosphatemic osteomalacia, the degree of osteoid accumulation, both osteoid surface and thickness, is reported to be much greater than in vitamin D deficiency osteomalacia [29,34,35]. Furthermore, the osteoid indices return to normal after successful therapy in vitamin D deficiency osteomalacia [36], but not in X-linked hypophosphatemic osteomalacia [34,37].

## 6. Bone mineral density distribution in osteomalacia

Bone strength is determined by its intrinsic material properties, and therefore the mineral content of the bone matrix plays a critical role in determining bone

**FIGURE 62.5** Goldner's Trichrome staining (light microscopy) demonstrating broad seams of pink stained areas corresponding to non- or poorly mineralized matrix and regions with blurred pink-green transition (black arrows), next to mineralized matrix (green) [31].

stiffness, strength, and toughness [38]. In contrast to bone mineral density (BMD) as assessed by standard densitometry (DXA) *in vivo*, which is an estimate of the total amount of mineral in a scanned two-dimensional area of whole bone, bone mineral density distribution (BMDD) as assessed by quantitative backscattered electron imaging (qBEI) *ex vivo* describes the mineral content of bone matrix throughout the bone biopsy sample [38].

Human cortical and trabecular bones are formed by individual osteons and bone packets, respectively, sometimes called basic structural units (BSU). The mineral content in BSUs varies depending on the time since its deposition, which contributes to local variation in material properties of bone, which was first quantified using microradiography [39]. Subsequently, more advanced and sensitive techniques, such as qBEI, have been developed [40,41]. Micrometer-scale variations in mineral content throughout the bone tissue have been reported using a histogram curve designated BMDD [42]. The characteristic parameters of the histogram include  $C_{MEAN}$  (the average calcium content in the bone volume of investigation),  $C_{PEAK}$  (the most frequent calcium content),  $C_{WIDTH}$  (the width of the calcium content distribution),  $C_{LOW}$  (the amount of lowly mineralized bone areas), and  $C_{HIGH}$  (the amount of highly mineralized bone areas) [43].

BMDD reports mineral content in small pixels or voxels within the area of investigation [43], which is far superior to the BMD as assessed by dual-energy X-ray absorptiometry (DXA) measuring areal BMD ( $\text{g}/\text{cm}^2$ ) or quantitative computed tomography (qCT) measuring volumetric BMD ( $\text{g}/\text{cm}^3$ ). DXA and qCT estimate the total amount of mineral in a scanned whole bone including all its cavities and do not distinguish any local variations in mineral content. BMDD is reported to be essentially constant in healthy adult cancellous bone irrespective of gender, ethnicity, and biopsy site, making it a more sensitive means to detect even small changes in mineralization due to bone disease or therapeutic intervention [43]. Deviations in the histogram toward the left or right indicate hypo- or hypermineralization, respectively [38]. Individual BMDD must be compared with data obtained from similar device due to the variation in reference curves depending on the electron source used in the scanning electron microscope (SEM) [44].

In osteomalacia, the BMDD curve is broader (indicating heterogenous mineralization) and shifted to the left (indicating lower mineralization) [38]. Fig. 62.6 demonstrates back scattered electron images of a 6-month-old infant with severe nutritional rickets, demonstrating areas of poor mineralization with the BMDD curve shifted toward lower mineral content, with increased width ( $C_{WIDTH} + 55\%$ ) due to increased heterogeneity in mineralization, and markedly increased fraction of poorly mineralized matrix ( $C_{LOW} + 640\%$ ) [31]

compared with the reference data from older children aged 1.5–23 years [45].

Similar to nutritional osteomalacia, individuals with other forms of rickets or osteomalacia including X-linked hypophosphataemia [46] and hypophosphatasia [47] also have a BMDD curve shifted toward lower mineralization. The BMDD curve in individuals with X-linked hypophosphatemia demonstrates lower peak and increased areas of low and heterogenous mineralization, which improves following treatment with phosphate supplements and active vitamin D [46] but does not completely reverse, and residual defects in mineralization are evident after stopping treatment [34]. In individuals with hypophosphatasia, in addition to abnormal trabecular microarchitecture, an increased number of osteoblasts compared with healthy controls or with individuals with other types of osteomalacia have been reported [47]. Following treatment with asfotase alfa (human recombinant tissue-nonspecific alkaline phosphatase) in hypophosphatasia, only minor improvements of bone microarchitecture are reported but a remarkable reduction in osteoid parameters [48]. After 2 years of asfotase alfa treatment, a significant reduction in the mineralization heterogeneity seen at baseline has been noted [48].

## 7. Radiological features of rickets and osteomalacia

Rickets is a radiological diagnosis (with typical biochemical and clinical features) and is evident at the metaphyses of rapidly growing bones. Signs of rickets are most evident around the wrist particularly the ulna [49], the anterior ends of the middle ribs, the proximal femur, and the distal tibia. Three stages of rickets have been described [50,51], and radiological changes are said to appear in stage two when hyperparathyroidism and hypophosphatemia secondary to increased phosphaturia are established, but features become more prominent in stage 3 [50–52] as depicted in Fig. 62.7. Although the initial stage is that of calcium deprivation, this is not manifesting clinically as hypocalcemia due to the compensatory mechanisms that come into play with secondary hyperparathyroidism [elevated parathyroid hormone (PTH)] [51]. Only those children with high calcium demand, such as infants or adolescents, are likely to present in this stage with hypocalcemic features [51,53]. In a prospective national survey of nutritional rickets in the United Kingdom and Ireland, radiological rickets was only recorded in 67% ( $n = 72/107$ ) of the children presenting with clinical and biochemical signs of rickets [54]. Similarly, another national survey determining the incidence of hypocalcemic seizures secondary to vitamin D deficiency found that of the 33%

**FIGURE 62.6** (A) and (B) illustrate backscattered electron images of the iliac bone sample of an infant with severe nutritional rickets [31]. The *dark gray* surface shows low mineral content in, *bright gray* indicates normal/high mineral content, and black is unmineralized matrix. Areas highlighted in Red (B) represent increased primary mineralization, i.e., areas mineralized below 17.68 wt% calcium, corresponding to the fifth percentile of the adult reference range (CaLow) [45]. The BMDD curve (C) is shifted toward lower mineral content compared with normative data from older children [45].

**FIGURE 62.7** Stages of calcium deprivation leading to nutritional rickets and osteomalacia [52].

( $n = 30/91$ ) who had radiographs taken, 77% (23/30) showed evidence of rickets [55]. Similar to the delayed appearance of signs of rickets on radiographs in this pathological process, complete healing of radiological rickets following treatment also takes time. On average, it takes around 3–6 months for complete radiological healing [56].

## 8. Radiographic differences between various forms of rickets

### 8.1 Radiological features of nutritional rickets

Rickets is most easily diagnosed on plain radiographs, and the classic signs include splaying, fraying, and cupping of the metaphyseal ends (Figs. 62.8 and 62.9). Pathologically, although expansion of the zone of hypertrophic chondrocytes is one of the earliest signs of rickets, it is not possible to identify this on radiographs at the onset of disease. Generally, the metaphysis and the growth plate need to be assessed separately. In the early phase of nutritional rickets, the growth plate, which appears as the radiolucent (unmineralized) gap between the mineralized metaphysis and epiphysis, widens [57]. The metaphysis, during evolution of rickets, will continuously demineralize due to PTH-induced osteoclastogenesis and thus become more and more radiolucent. Similarly, the expansion of the metaphyses or splaying becomes more evident with progressive disease. Splaying is clinically evident as swollen

**FIGURE 62.8** Wrist radiograph (anteroposterior view, left and lateral view, right) of a 3-year-old child presenting with bowing of the legs (25(OH)D 8.2 nmol/L, ALP 1003 IU/L, adjusted calcium 1.3 mmol/L, phosphate 1.2 mmol/L and PTH 136 ng/L). The radiographs demonstrate clear signs of cupping, fraying, and splaying at the metaphyses of the ulna and radius. Secondary hyperparathyroidism demonstrates a double contour in the metaphysis and diaphysis. Additionally, the diaphyseal shaft demonstrates periosteal elevation on the external cortex.

**FIGURE 62.9** Wrist radiographs of a 16-month-old presenting with hypocalcemic seizures secondary to nutritional vitamin D deficiency (25(OH)D 8.4 nmol/L, ALP 1702 IU/L, adjusted calcium 1.2 mmol/L, phosphate 1.3 mmol/L and PTH 265 ng/L). The image on the left shows classic signs of rickets of metaphyseal widening, splaying, and cupping at the ulna and radius. There is significant demineralization of the growth plate and the diaphysis. Wrist radiograph on the right shows healing of rickets (25(OH)D 164 nmol/L, ALP 343 IU/L, adjusted calcium 2.3 mmol/L, phosphate 1.58 mmol/L, and PTH 31 ng/L) following treatment with ergocalciferol and calcium. Following treatment (right), the opaque line of mineralization representing the zone of provisional calcification is visible.

joints at the wrist and ankle and as rachitic rosary at the costochondral junction [31,58]. One of the earliest radiological signs is the fading of the opaque line of zone of provisional calcification due to the decrease in mineralization of the terminally differentiated chondrocytes and cartilage. Reappearance of the line (Fig. 62.9) is also one of the earliest signs of healing rickets [49]. The loss of distinction between cartilage and metaphyseal bone along with extension of tongue like cartilage into the metaphysis (as described earlier in the growth plate histology section) results in indistinct margins or a frayed radiographic appearance. These changes are more prominent in the middle of the growth plate, which leaves a rim of calcified tissue surrounding the growth plate giving the concave or cupped appearance at the end.

A 10-point radiological severity score (RSS, or Thacher score) assessing the degree of metaphyseal fraying and cupping and the proportion of the growth plate affected at the wrists (radius and ulna) and knees (femur and tibia) is recognized as a valid outcome measure to quantify the changes of nutritional rickets [59]. Rickets severity on radiographs is reported to be correlated to serum ALP levels [59]. Some degree of subjectivity remains in reporting especially when changes of rickets are borderline or when there are alterations in the plane of the radiographs in relation to the metaphyseal–physeal junction giving a concave

appearance to the metaphyses [51,59]. Similarly, other radiological signs of rickets such as osteopenia can be subjective and dependent on the radiographic technique. The osteoclastic resorption resulting from secondary hyperparathyroidism may be evident as subperiosteal erosion along the shaft of long bones but is a less common radiological feature of rickets compared with metaphyseal changes described before [51]. Hyperparathyroidism causes osteoclastic resorption of the Haversian canals within the cortex of the bones referred to as intracortical tunneling appearing as translucent lines on radiographs. Radiographically, this causes linear translucencies within the cortex. Excessive bone resorption in the skull vault causes the mottled texture of alternating areas of lucency and sclerosis referred to as pepper-pot skull or “salt and pepper” (Fig. 62.10) [60].

Chest radiographs are frequently done in children presenting with various health conditions and may be helpful in identifying signs of rickets and other metabolic bone conditions incidentally. Some of the common features, which lead to suspicion of bone disease or rickets, may include acute or healing rib fractures, generalized demineralization of the ribs (Fig. 62.11), or signs of rickets in the shoulder joints (Fig. 62.11). Additionally, enlarged cardiac shadow on chest radiographs

may be suggestive of cardiac failure due to dilated cardiomyopathy in infants with severe rickets (Fig. 62.12). All infants presenting with severe nutritional rickets must have their cardiac function evaluated [31,61].

## 8.2 Radiological features of osteomalacia

Following the closure of growth plates at the end of longitudinal growth, osteomalacia becomes much more difficult to spot on radiographs. Radiographic features of adolescent and adult osteomalacia can only be detected in the most severe cases. The pathognomonic feature of osteomalacia is the Looser zone fracture (pseudofracture, Milkman fracture) Fig. 62.13 [63]. Looser zone fractures are said to occur at sites of stress in the skeleton, which include the femoral neck, the medial side of the proximal femur, the pubic rami, the lateral border of the scapula, and the ribs. These must be differentiated from atypical insufficiency fractures occurring in osteoporotic bones [64] and traumatic fractures. Bones in osteomalacia are soft due to demineralization and therefore deform easily leading to varus (bowing) and less commonly valgus deformities of the lower limbs. Additional features of osteomalacia include coarse trabecular pattern at the diaphysis, biconcave vertebral deformity, protrusio acetabulae (deformity of the femoral head leading to loss of the normal acetabular margin), and triradiate appearance of the pelvis. Most importantly, clinical signs of osteomalacia includes proximal muscle weakness, with inability to rise from the floor unaided, nonspecific musculoskeletal pain, and these signs are accompanied by the typical biochemical derangement of ALP, PTH, calcium, and/or phosphate. Identifying osteomalacia based on clinical and biochemical features is possible and will help explore the hidden burden of osteomalacia enabling appropriate public health measures. Certain clinical and biochemical diagnostic criteria for identification of osteomalacia without the need for invasive bone biopsies have been proposed [65,66]. A diagnosis of osteomalacia can be made in the presence of musculoskeletal symptoms along with low serum 25(OH)D, high ALP and/or PTH, and low calcium and/or phosphate although these can be late features [65,66].

**FIGURE 62.10** Skull CT scan of an adolescent demonstrating widespread areas of alternating lucency and sclerosis with focal erosive changes in the greater wing of the left sphenoid bone (arrow). The subject had learning difficulty and restrictive eating disorder presenting with multiple and severe nutritional deficiencies including vitamin A, folate, vitamin B12, and vitamin D (25.8 nmol/L). Biochemical parameters at the time of imaging included 25(OH)D 56.2 nmol/L (on 400IU cholecalciferol supplements for 5 months), ALP 293 IU/L, adjusted calcium 2.27 mmol/L, phosphate 1.28 mmol/L, and PTH 133 ng/L. History of dietary calcium deficiency was positive and calcium supplements commenced.

## 8.3 Radiological signs of non-nutritional rickets/osteomalacia

### 8.3.1 Vitamin D–dependent rickets

To date, five distinct types of vitamin D–dependent rickets (VDDR) have been described (type 1a/b, 2a/b, 3) [67]. Apart from type 2b, all are known to be heritable with distinct genetic defects in vitamin D synthesis or degradation. The radiological features of rickets at the

**FIGURE 62.11** Incidental finding of generalized demineralization of the ribs and rachitic changes at the humerus (*left*) in a 6-month-old infant presenting with a respiratory tract infection. Further radiographs of the knee (*right*) and biochemical investigations (25(OH)D 59 nmol/L, ALP 1000 IU/L, adjusted calcium 2.46 mmol/L, phosphate 1.23 mmol/L, and PTH 24 ng/L) confirmed a diagnosis of hypophosphatemic rickets due to a very rare cause of elemental formula use [62].

**FIGURE 62.12** Chest radiograph of a 2-month-old baby demonstrating an enlarged heart due to congestive cardiac failure and dilated cardiomyopathy secondary to severe nutritional rickets (25(OH)D < 7.5 nmol/L, ALP 786 IU/L, adjusted calcium 1.6 mmol/L, phosphate 2.15 mmol/L dropped to 0.7 on initiation of intravenous calcium indicating a degree of PTH resistance, PTH 288 ng/L).

growth plate, metaphyses, and those of hyperparathyroidism along the diaphyseal shafts in VDDR are very similar to those of nutritional (vitamin D deficiency and calcium deficiency) rickets (Fig. 62.14).

### 8.3.2 Hypophosphatemic rickets/osteomalacia

Radiological feature in hypophosphatemic forms of rickets are distinctly different from those of nutritional rickets. X-linked hypophosphatemia (XLH) caused by mutations in the PHEX gene is the most common form of inherited hypophosphatemia. In XLH, the underlying pathophysiology is excess fibroblast growth factor 23 (FGF23), leading to hyperphosphaturia and hypophosphatemia. Bone mineralization in XLH is better preserved when compared with nutritional rickets due to the lack of secondary hyperparathyroidism. The

**FIGURE 62.13** Hip radiograph of a 11-year-old with Down's syndrome and global developmental delay who presented with hip pain and reduced mobility. Radiographs revealed genu valgum and bilateral Looser zone fractures (*broad arrows*) and evidence of rickets at the metaphyses (*narrow arrows*). Since he had not shown adequate response in biochemical and radiological parameters to vitamin D2 supplements (25(OH)D 52.0 nmol/L, ALP 2025 U/L, adjusted calcium 1.21 mmol/L, phosphate 2.11 mmol/L, and PTH 294 ng/L), genetic workup was initiated, which revealed VDDR1.

metaphyses are wider, and the cortices appear rather dense on X-rays (Fig. 62.15). An unusual radiological feature of XLH is the high radial trabecular vBMD (especially in treated patients) and rather low cortical vBMD measured by peripheral quantitative computed tomography (pQCT), despite histological osteomalacia in both bone compartments [34]. High-resolution peripheral quantitative computed tomography (HR-pQCT) findings in XLH patients compared with controls indicates lower trabecular numbers, greater trabecular separation, and higher trabecular network inhomogeneity with the tibia more affected than the radius [68–70]. A higher trabecular thickness in the tibia has also been reported, especially in children [71].

**FIGURE 62.14** A 11-month-old child, of consanguineous parents of Asian origin, presented with right limb pain after fall from a sofa. The initial radiograph (A) revealed no fractures but florid rickets (fraying and splaying of femoral metaphysis) was noted and a diagnosis of nutritional rickets made (25(OH)D 18.5 nmol/L, ALP 4280 IU/L, adjusted calcium 1.6 mmol/L, phosphate 0.94 mmol/L, PTH 981 ng/L). Reimaging a few weeks later due to ongoing pain revealed a fracture (B) of the right femoral shaft and evidence of ongoing rickets. Lack of expected response of biochemical parameters to treatment led to the suspicion of vitamin D–dependent rickets (VDDR) and 1-alpha hydroxylase deficiency confirmed. Radiological healing of rickets (C) and normalization of biochemical parameters was noted following treatment with alfacalcidol.

**FIGURE 62.15** Knee (A) and wrist (B) radiograph of a 3-year-old child with X-linked hypophosphatemic rickets (serum phosphate 0.7 mmol/L, ALP 777 IU/L, calcium 2.2 mmol/L, parathyroid hormone 6 ng/L) who presented with bowing of the legs, leg pain, and recurrent dental abscesses. Knee radiograph (*left*) demonstrates wide metaphyses and thickened cortex. The metaphyseal changes of rickets in the femur (A) are more prominent medially. The rachitic changes in XLH are usually more prominent at the knee than at the wrist (B). Aged 9 years, despite being on conventional therapy with oral phosphate supplements and vitamin D analogue, the child demonstrated ongoing varus deformity of the lower limbs with bilateral femoral and tibial bowing (C).

Clinically, genu varum is common in XLH, and the distal femoral and proximal tibial physes are often more affected medially than laterally. The RSS scoring system devised for nutritional rickets has also been used to evaluate disease severity and response to treatment in patients with XLH [72,73]. Despite early and lifelong treatment with phosphate supplements and active vitamin D analogs in XLH, a significant disease-related morbidity remains [73,74]. The short-term

outcomes with newer therapeutic agents such as burosumab (anti-FGF23 antibody) are promising, demonstrating radiological healing of rickets [75] (Fig. 62.16); however, long-term outcomes in the real-world remain under review. Children with XLH also typically develop dolichocephaly and craniosynostosis [76]. Radiographs in untreated, or previously treated, adults may exhibit Looser zone fractures, residual limb deformities, osteoarthritis, and enthesopathies [77].

**FIGURE 62.16** Radiograph of the left knee of an 8-year-old with X-linked hypophosphatemia demonstrating metaphyseal widening and irregularity (A) on conventional therapy with oral phosphate supplements and vitamin D analogue (commenced shortly after birth). Radiological healing of rickets (B) was noted after 2 years of treatment with burosumab (anti-FGF23 antibody).

### 8.3.3 Hypophosphatasia

Hypophosphatasia (HPP) is a multisystemic bone disease caused by dominantly or recessively inherited *ALPL* gene mutations. The resulting deficiency in TNSALP reduces mineralization in growth plates, bones, and teeth and causes the hallmark biochemical feature of decreased serum ALP concentrations. Clinical variability of the condition is substantial, from severe perinatal to adult-onset disease. Generally, the earlier the presentation, the more severe the phenotype. Histological assessment of growth plates [78] and adult bone [47] confirm rickets and osteomalacia, respectively. Radiological features of the most severe, perinatal, and infantile forms of HPP are generalized hypomineralization and rickets. The typical radiological features of childhood-onset HPP include characteristic tongue-like metaphyseal radiolucency (Fig. 62.17). Other radiological features include metaphyseal fraying and widening and metadiaphyseal sclerosis. There is irregularity of the provisional zone of calcification with distal metaphyseal demineralization and a transverse subphyseal band of lucency [66]. Severe forms of the condition are associated with craniosynostosis.

## 8.4 Differential diagnosis of rickets from an imaging perspective

Above, we have described the radiological features of the classical forms of rickets. Other “nutritional” forms of rickets and osteomalacia due to deficient calcium supply or malabsorption manifest in cholestatic liver disease (where treatment is incredibly challenging [79]),

**FIGURE 62.17** Radiographs of a child with infantile hypophosphatasia pre- (A) and post- (B) treatment with asfotase alfa (recombinant, bone-targeted, human tissue-nonspecific alkaline phosphatase). The pretreatment radiograph (A) demonstrates generalized demineralization with the characteristic tongue like lucency in the femoral metaphysis. There is distal metaphyseal demineralization and a transverse subphyseal band of lucency potentially representing islands of hypertrophic chondrocytes that are migrating down the metaphysis waiting to be replaced by bone during bone remodeling.

inflammatory bowel disease, short bowel syndrome, or celiac disease. In addition, renal failure, via multiple factors including deficient 1-hydroxylation of 25(OH)D, causes rickets-like features on X-rays. Fig. 62.18 shows comparative knee X-rays in classical forms of rickets and in hepatic and renal osteodystrophy.

Rickets is often suspected in children with bowed legs and is a common reason for referral to metabolic bone specialists. The typical differentials in children under 3 years of age include physiological bowing and Blount's disease [81], a transient condition of unknown origin. Since these infants are typically early walkers (prior to 12 months) and often overweight, one theory for their bowed legs is immature biomechanical adaptability. Radiologically, there are no signs of rickets but metaphyseal beaking of the proximal medial tibial metaphysis is present (Fig. 62.19).

Severe primary growth plate disorders (skeletal dysplasias) such as achondroplasia or spondyloepimetaphyseal dysplasia may also mimic rickets radiologically although these conditions come with typical disproportionate short stature or dysmorphic features. Schmid metaphyseal chondrodysplasia, a type X collagen disorder, is associated with disproportionate short stature, bowed legs, and radiological signs reminiscent of rickets (Fig. 62.20). Rickets is also a paradoxical complication specific to autosomal recessive infantile osteopetrosis type 1 (*TCIRG1* gene mutation) caused by the inability of osteoclasts to resorb primary spongiosa, a phenomenon called osteopetrorickets [82,83].

**FIGURE 62.18** Knee X-rays with typical signs of rickets in patients with different types of rickets. (A) VDDR1, (B) renal osteodystrophy, (C) hepatic osteodystrophy, (D) XLH, (E) HPP [80].

**FIGURE 62.19** Radiograph of a 21-month-old girl with Blount's disease presenting with genu varum and waddling gait. Radiographs do not show signs of rickets but metaphyseal beaking of the proximal medial tibial metaphysis is noted.

As a general rule, when rickets is suspected, a thorough clinical and biochemical workup for hypomineralization disorders (serum ALP, PTH, 25(OH)D, calcium, phosphate, liver and renal function) is required. In the setting of normal biochemical workup primary growth plate disorders should be suspected and genetic workup considered.

## 9. Imaging choice in rickets and osteomalacia

### 9.1 Children

Classically presenting patients with nutritional rickets will display clinical signs such as leg bowing, swelling of wrists and ankles, rachitic rosary, muscle weakness, and hypocalcemic complications such as

**FIGURE 62.20** Radiograph of a 3-year-old boy presenting with bowing of legs and rickets-like changes on growth plates and metaphyses. Clinical examination and radiographs revealed rhizomelic shortening with rickets-like changes at the metaphyses. Biochemical evaluation was unremarkable (25(OH)D 93.9 nmol/L, ALP 235 IU/L, adjusted calcium 2.48 mmol/L, phosphate 1.57 mmol/L, and PTH 15 ng/L) raising the suspicion of Schmid-type metaphyseal chondrodysplasia, which was confirmed with a heterozygous *COL10A1* mutation.

seizures that should lead to rapid diagnosis purely based on clinical criteria and typical biochemistry. The minimal imaging required to confirm the diagnosis is an X-ray of wrist and knee. No further imaging techniques apart from standard X-rays are required. Patients suspected of XLH or HPP also require knee and wrist X-rays. In young children with XLH and HPP, head

circumference and skull shape need monitoring for evidence of craniosynostosis and further X-ray or CT imaging may be required for confirmation.

## 9.2 Adolescents

Adolescents with nutritional rickets/osteomalacia typically present with proximal muscle weakness and sometimes with hypocalcemic complications such as tetany. In adolescents who are close to reaching final height, growth plate activity is slow and radiological rickets (as well as the concomitant osteomalacia) can no longer be detected on wrist or knee X-rays. Although MRI may be able to detect metaphyseal abnormalities adjacent to the growth plates as demonstrated in XLH [84], MRI is neither commonly available, nor easily accessible, nor routinely indicated. Since the diagnosis can be easily made or highly suspected from clinical presentation and typical biochemistry, no further imaging is indicated. Localized pain, in particular around the thigh, should trigger further X-ray and MRI investigations to detect Looser zone fractures, which are labeled pseudofractures [85]. Confirmation of the diagnosis of suspected osteomalacia also comes with normalization of clinical symptoms and biochemistry following treatment.

## 9.3 Adults

The presentation of nutritional osteomalacia in adults can be classical with severe muscle weakness, Looser zone fractures (stress or pseudo-fractures) and typical, with typical biochemistry (elevated ALP and PTH). However, in the absence of fractures, the other signs of osteomalacia—general fatigue, malaise, muscle weakness, and pain—are nonspecific. The medical literature is surprisingly sparse on nutritional osteomalacia, even in areas where nutritional rickets is endemic in children, which may indicate that osteomalacia in adults remains largely undiagnosed [66].

Osteomalacia is regarded as a clinical diagnosis when, in fact, there are no established noninvasive diagnostic criteria. To date, the diagnosis of osteomalacia requires taking a bone biopsy. In clinical practice, typical Looser zone fractures or pseudo-fractures on X-rays, together with typical clinical and biochemical criteria, would make osteomalacia very likely. However, in the absence of fractures and validated diagnostic criteria, clinicians will be inclined to conduct a bone density (DXA) scan as osteoporosis is and remains the most common bone disease in adults. DXA, however, is unable to differentiate disorders of bone mineralization (osteomalacia) from those of reduced bone mass/structure (osteoporosis). Hence, this imaging method has no role in the specific diagnosis of osteomalacia; it will merely confirm

reduced bone mass. Similar to DXA, high-resolution pQCT will demonstrate low cortical and trabecular thickness and density but will not be able to differentiate osteomalacia from osteoporosis radiologically as seen in conditions such as tumor-induced osteomalacia [86]. Hence, even with modern imaging techniques, osteomalacia can only be suspected clinically, and imaging does not increase diagnostic certainty.

Unfortunately, these diagnostic limitations have led to integration of osteomalacia into osteoporosis management in adults, while rickets is clearly separated from osteoporosis management in children. This shortfall of medical knowledge has resulted in recommendations that all adults with low bone mass receive vitamin D and calcium preparations as a nonpharmacological baseline therapy [87]. This appears justified in the sense that older adults frequently consume low amounts of dairy products and have low sun exposure. However, such substitution is not a therapy for osteoporosis but given to prevent osteomalacia and secondary hyperparathyroidism, which can further aggravate bone loss. In that respect, it is important to recognize that giving vitamin D to people with sufficient vitamin D and dairy intake (normal habitual bone mineral supply) will not increase bone mass [88]. Clinical diagnostic criteria for nutritional osteomalacia have been proposed that do not require imaging [65,66], but these need further validation.

Overall, X-rays remain the only imaging method relevant for detection of rickets. In adolescents and adults with suspected osteomalacia with typical clinical presentation and biochemical findings, no other imaging techniques can reasonably be employed (unless for detection of suspected pseudofractures).

## 10. Conclusion

Hypomineralization disorders can result from lack of minerals (calcium and/or phosphate), mineral suppliers (calcitriol) or facilitators of mineralization such as alkaline phosphatase and nutritional rickets due to vitamin D and/or dietary calcium deficiency remain the most common cause worldwide.

Accumulation of hypertrophic chondrocytes at the growth plate, resulting from hypophosphatemia and lack of apoptosis, leads to the classic radiological features of rickets—metaphyseal cupping, fraying, and splaying—and manifests clinically with swollen ankles or wrists and rachitic rosary in children. Osteomalacia manifests clinically as bowing leg deformities in children but largely remains undiagnosed in adults, rarely presenting with Looser zone fractures. Definitive diagnosis of osteomalacia is made on histomorphometry where reduced mineralization of the osteoid is evident as increased osteoid surface, thickness, and mineralization lag on

tetracycline labeling. The BMDD curve on quantitative backscattered electron imaging is shifted to the left. Further studies are required to establish less invasive clinical and biochemical diagnostic criteria for osteomalacia.

## 11. Summary points

- Rickets is a radiological diagnosis, and children usually present with acute hypocalcemic (seizures, dilated cardiomyopathy) or hypophosphatemic (muscle weakness, bowing of legs) signs.
- Clinical presentation of osteomalacia is less nonspecific and is best diagnosed on bone biopsy with increased osteoid surface, thickness, and mineralization lag on tetracycline labeling.
- Phosphate-regulated apoptosis of hypertrophic chondrocytes is activated via the caspase-9-mediated mitochondrial pathway. Lack of apoptosis leads to accumulation of hypertrophic chondrocytes, which leads to an expansion of the hypertrophic zone as the chondrocytes, previously arranged in columns, become disarrayed.
- Radiological changes of rickets occur when hyperparathyroidism and hypophosphatemia secondary to increased phosphaturia are established.
- The changes at the growth plate—cupping, fraying, and splaying result from accumulation of hypertrophic chondrocytes due to lack of apoptosis. Secondary hyperparathyroidism results in subperiosteal erosion along the shaft of long bones, which is usually seen in calcipenic rickets secondary to calcium or vitamin D deficiency.
- Characteristic metaphyseal tongue-like lucencies are evident in hypophosphatasia, and in X-linked hypophosphatemia, widened metaphyses with dense cortices are a feature.
- DXA scan is unable to differentiate disorders of bone mineralization (osteomalacia) from those of reduced bone mass/structure (osteoporosis).

<sup>1</sup>MRC/Wits Developmental Pathways for Health Research Unit, Department of Paediatrics, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa <sup>2</sup>Department of Paediatrics, Chris Hani Baragwanath Academic Hospital, Johannesburg, South Africa <sup>3</sup>Department of Family Medicine, Mayo Clinic, Rochester, MN, United States

## OBJECTIVES

- To present the epidemiology of nutritional rickets in children (including the metabolic bone disease of prematurity) and highlight its prevalence globally.
- To describe the various clinical presentations of vitamin D, dietary calcium and phosphorus deficiency rickets, and the influence of age and severity on these.
- To describe the characteristic perturbations in clinical chemistry associated with nutritional rickets and highlight how they differ from those associated with hypophosphatemic rickets due to renal phosphate loss.
- To outline the radiological changes associated with rickets and the use of the radiographic Rickets Severity Score in the assessment of rickets.
- To discuss the prevention and treatment of nutritional rickets, highlighting the need for global action in its prevention through possible supplementation and/or food fortification.

## Abbreviations

**1,25-(OH)<sub>2</sub>D** 1,25-Dihydroxyvitamin D  
**24,25-(OH)<sub>2</sub>D** 24,25-Dihydroxyvitamin D  
**25(OH)D** 25-Hydroxyvitamin D  
**IU** International units  
**ng/ml** Nanogram/milliliter  
**nmol/L** Nanomole/liter  
**PTH** Parathyroid hormone  
**TmP/GFR** Tubular maximum of phosphate/liter of glomerular filtrate

## Index terms

### Rickets

- pathogenesis
- diagnosis
- radiological changes
- biochemistry
- treatment
- prevention

### Vitamin D deficiency

### Dietary calcium deficiency

### 25-Hydroxyvitamin D

## 1. Introduction

Rickets is a clinical syndrome in children, resulting from failure of or delay in mineralization of the growth plate of growing bones. Of the numerous different causes, the majority can be grouped into three major categories: those that primarily result in a failure to maintain normal calcium homeostasis (calciopenic); those that primarily affect phosphate homeostasis (phosphopenic); and those that directly inhibit the mineralization process. Globally, rickets due to nutritional causes (which typically fall into the calciopenic group) remain the most frequent form of the disease. However, in a number of industrialized countries, such as the United States, the genetic forms of hypophosphatemic rickets are now probably more prevalent than nutritional causes outside the neonatal and infant periods, as a result of the fortification of foods with vitamin D and

the use of vitamin D supplements in at-risk groups. Nevertheless, the past 30 or more years have seen a resurgence of nutritional rickets primarily in dark-skinned minority communities in a number of developed countries.

## 2. Historical perspective

Although nutritional rickets is often considered to be a disease of industrialization, descriptions of rickets have been attributed to both Homer (900 BCE) and Soranus Ephesius (130 CE). Of interest is the recent report of a Neolithic skeleton of a young adult female excavated from a burial site in Scotland having deformities in keeping with those of childhood rickets [1]. The term “rickets” emerged in the hand-written “Receipt Books” of the Fairfax Family. The entry for February 25, 1632 has five remedies for “rickets in children”. The word “rickets” first appeared in print in 1634 when it figured in the Annual Bill of Mortality of the City of London for that year [2]. Perhaps the best early descriptions of rickets are provided by Daniel Whistler in 1645 and 5 years later by Francis Glisson (1650). It was described as a disease that occurred in young children, produced severe deformities, and was often fatal.

Rickets was well established in London before the industrial revolution [3]. The origin of rickets may relate to the widespread practice of wet nursing, where a wet nurse engaged in continuous breastfeeding, even nursing several children simultaneously [4]. Because the concentration of calcium in breast milk declines over the course of lactation, the calcium intake of very young infants who were wet-nursed was probably considerably less than required for adequate bone mineralization. The appearance of nutritional rickets among infants in the 17th century could have resulted from both restricted calcium intake and pollution related to burning coal in the cities [2].

With the migration of large numbers of people from rural to urban areas at the time of the industrial revolution, the disease became associated with poverty and overcrowding in the developing urban slums. In 1822, Jędrzej Sniadecki proposed that the direct action of the sun was important in the cure and prevention of rickets. Contrasting the frequency of rickets in the British Isles with the rarity of rickets in Asian countries, Theobald Palm in 1890 proposed that sun exposure could prevent rickets [5]. A number of studies in the late 19th and early 20th centuries documented the almost universal prevalence of rickets in young children in cities in northern Europe (for example, in Glasgow [6] and Vienna [7]). Harriett Chick noted that rickets had a marked winter incidence; that protection in winter could be given by diet with added cod liver oil; and that infants in the first

6 months of life were very susceptible to rickets [7]. However, with the realization of the importance of ultraviolet light in preventing nutritional rickets and the discovery and isolation of vitamin D in the first quarter of the 20th century [8] ([9] cf. Chapter 1 (Historical)), programs were introduced to prevent vitamin D deficiency.

In the United Kingdom, a number of foods were fortified with vitamin D during World War II. This led to a rapid reduction in the number of children diagnosed with rickets, but in the following years, the incidence of idiopathic hypercalcemia rose in infants, which was attributed to uncontrolled fortification of various foods (especially milk and cereals), leading to daily vitamin D intakes of 100 µg (4000 IU) or more [10,11]. There has been a resurgence of cases of rickets in the United Kingdom after reducing the levels of mandatory fortification in 1955, and lowering recommended levels of supplementation, in response to cases of hypercalcemia [12].

The prevalence of vitamin D deficiency and nutritional rickets has increased, particularly among the immigrant South Asian (Indian and Pakistani) population in the United Kingdom, and this has become a politically divisive issue, centered on the role of social welfare programs in addressing the resurgence. Rickets was framed as a disease of a transplanted minority or as an indicator of poverty among the majority [12].

In the United States, the universal fortification of milk with vitamin D at 400 IU/quart from the 1930s had almost eradicated nutritional rickets except in families who exclude milk from their diets or in infants who are breastfed for extensive periods without supplementation [13]. However, as had possibly occurred in the United Kingdom, a few cases of vitamin D toxicity have been reported as a result of the lack of monitoring of the fortification process [14]. In central Europe, rickets had been effectively prevented in infants and young children by the intermittent administration (every 3–5 months for the first 2 years of life) of high doses of vitamin D (“stoss therapie”) [15].

## 3. The epidemiology of vitamin D deficiency and nutritional rickets

Discussion and debate continue concerning the definition of vitamin D deficiency and the best methods for determining vitamin D status. Since the descriptions of the first assays to measure serum concentrations of vitamin D and/or its metabolites in the early 1970s, 25-hydroxyvitamin D (25(OH)D) has been the metabolite used to define vitamin D status, as its serum concentrations are relatively stable (half-life 2–3 weeks), are not regulated to any great extent except by substrate concentration, and reflect vitamin D intake through the diet and synthesis in the skin [16,17]. In the pediatric literature,

vitamin D deficiency has in the past been defined as that range of 25(OH)D concentrations associated with the development of rickets and osteomalacia, which have generally been accepted to occur at serum concentrations of  $<10\text{--}12\text{ ng/mL}$  or  $<25\text{--}30\text{ nmol/L}$  [18,19]. However, there is now considerable interest in the less obvious effects of vitamin D on bone mass, parathyroid hormone secretion and in the nonclassical actions of vitamin D, such as its role in immune regulation, and in the prevention of allergic and autoimmune diseases, diabetes, cardiovascular disease, and certain cancers [20,21]. This has complicated the determination of optimal vitamin D status, as there are few randomized controlled trials designed to assess optimal 25(OH)D concentrations in children taking into consideration these extraskeletal functions. A recommended dietary allowance (RDA) for vitamin D was set by the US National Academy of Medicine (formerly Institute of Medicine). Vitamin D requirements are variable across the population, and they determined the estimated average requirement (EAR) of vitamin D for the population corresponded to a 25(OH)D level of  $40\text{ nmol/L}$  with half requiring more than this and half requiring less. Based on a normal population distribution, 97.5% will have their vitamin D needs met at a serum level of  $50\text{ nmol/L}$ , and the RDA was set to achieve that level of 25(OH)D [19]. Global consensus recommendations have been developed for the prevention and management of nutritional rickets [22]. The Indian Academy of Pediatrics has developed similar recommendations [23]. These groups equate vitamin D deficiency to  $25(\text{OH})\text{D} < 30\text{ nmol/L}$ , vitamin D insufficiency to levels between  $30$  and  $50\text{ nmol/L}$ , and vitamin D sufficiency to concentrations  $>50\text{ nmol/L}$ .

Vitamin D deficiency is a prerequisite for the development of nutritional rickets in a large proportion of infants and young children. Thus the disease is typically associated with a lack of ultraviolet light, prolonged breastfeeding, and inadequate dietary vitamin D intake. As commonly ingested foods are generally deficient in vitamin D, in the absence of food fortification with vitamin D, the normal diet contributes little vitamin D [24], and adequate skin exposure to ultraviolet radiation is essential for adequate vitamin D status [25] (cf. Chapter 2—photobiology and evolution of vitamin D). Consequently, rickets occurs most frequently in infants before they are able to walk and get out-of-doors, and in children living in countries at the extremes of latitude, living in dwellings that prevent ready access to sunlight exposure or in communities in which social or religious customs prevent adequate sunlight exposure through extensive skin coverage by clothing or through the practice of *purdah*.

Vitamin D deficiency rickets is most prevalent in children under 2 years of age, with a peak incidence

between 6 and 18 months [26,27]. The disease is uncommon in infants under 3 months of age, because 25(OH)D readily crosses the placenta [28,29], thus providing the newborn infant with some protection against vitamin D deficiency if maternal vitamin D status is normal [28] (cf. Chapter 38—pregnancy and lactation). Because serum 25(OH)D has a half-life of only 2–3 weeks, serum levels fall rapidly after birth unless additional sources of vitamin D are obtained by the young infant [30]. Neonatal or congenital rickets has been described in infants born to mothers who are themselves vitamin D deficient [31–33], and neonatal hypocalcemia occurs more commonly in neonates born to vitamin D-deficient mothers [34]. The role of maternal vitamin D status during both pregnancy and lactation in predisposing infants to vitamin D deficiency has become clear [28]. Furthermore, many mothers worldwide are frankly vitamin D deficient (up to 80% in some communities [35,36]), despite some being given supplements during pregnancy [37–39]. Maternal vitamin D deficiency is associated with vitamin D deficiency rickets in their infants. In a study from the Middle East, vitamin D deficiency was identified in nearly 100% of mothers whose infants had nutritional rickets, compared with just over 50% of the mothers whose infants did not have rickets [40]. There are several reasons for this association: infants at birth are born with vitamin D stores that are dependent on the maternal vitamin D status, the breast milk of mothers who are vitamin D deficient contains negligible amounts of vitamin D, and finally the social and environmental factors that produce vitamin D deficiency in the mother are similar for the infant.

Vitamin D deficiency rickets has been noted to occur more commonly in boys than girls [41–43]; however, the mechanism for this remains unclear. It has been suggested that vitamin D deficiency rickets might be an hereditary disease, which manifests itself only under adverse environmental circumstances [42,44,45]. In a study of infants with rickets and their parents [44], urinary excretion of  $\alpha$ -amino acids was increased in one-third of the infants a long time after the rickets had healed, many of the parents had increased amino acid and phosphorus excretion, and a good correlation was found between the excretion of individual amino acids by an infant and its parents. The authors suggested that these findings indicate a genetic factor playing a role in predisposing a child to rickets; however, the mode of inheritance is unclear.

Polymorphisms of the vitamin D receptor (*VDR*) gene might play a role in predisposing infants and children to rickets. In a study of Turkish and Egyptian infants with rickets, the prevalence of the *F* allele of the *VDR* start codon was greater in children with rickets than controls [46], similar to findings in Nigerian children with dietary

calcium deficiency rickets [47] and in Asian children with nutritional rickets. Furthermore,  $1,25(\text{OH})_2\text{D}$  concentrations in Egyptian children were lower in those who were *FF* homozygotes. In the same group of children, it was suggested that the *B* allele might predispose an individual to vitamin D deficiency. However, in Indian and Mongolian studies, no relationships between rickets and various *VDR* polymorphisms were found [48,49].

*CYP2R1* is the major, but not exclusive, hepatic 25-hydroxylase responsible for the hydroxylation of the parent vitamin D to  $25(\text{OH})\text{D}$  [50]. Genetic polymorphisms of *CYP2R1* account for some of the individual variability of circulating  $25(\text{OH})\text{D}$  values in the population [51,52] and may determine vitamin D requirements in the general population. Inactivating mutations in *CYP2R1* can lead to vitamin D–deficient rickets resulting from impaired 25-hydroxylation of vitamin D [53,54] (the disease classified as vitamin D–dependent rickets, type 1B [VDDR1B, MIM 600081]).

In the early literature, breastfeeding was reported to be protective against rickets [55]. More recently, however, it has been described as a risk factor for the development of rickets [56–60]. In recent years, specifically designed breast milk substitutes have replaced natural cow's milk as the major source of nutrients for the non-breastfed infant. This alteration in feeding patterns may account for the apparent change in risk associated with breastfeeding for several reasons; firstly, breast milk substitutes are fortified with vitamin D at 400 IU/L, while natural cow's milk (unless fortified) contains little or no vitamin D [61]; secondly, the calcium:phosphorus ratio in breast milk substitutes (ratio ~2:1) is more appropriate than that in cow's milk (ratio ~1:1) for optimizing intestinal calcium absorption; and thirdly, although breast milk usually contains only small quantities of vitamin D or its metabolites (between 20 and 65 IU/L), the content is dependent on the vitamin D status of the mother [61–64]. However, there is evidence that vitamin D metabolites may cross into breast milk from the mother in sufficient quantities to maintain normal serum concentrations of  $25(\text{OH})\text{D}$  in the suckling infant if the mother receives vitamin D supplements in high doses (2000–6400 IU/day) [65–67]. A randomized controlled trial has been conducted supplementing lactating mothers with vitamin  $\text{D}_3$  at 6400 IU/day. The breastfed infants' vitamin D status was maintained through the increased breast milk vitamin D content at levels similar to those obtained by supplementing the infant directly with 400 IU/day [66], without any evidence of adverse events. Results of studies are conflicting concerning the relative concentrations of vitamin D and  $25(\text{OH})\text{D}$  in breast milk; however, what is known is that concentrations are higher in hindmilk than foremilk and correlate with maternal vitamin D status [63,68–70]. A single maternal oral dose of vitamin  $\text{D}_3$  150,000 IU was

equivalent to 5000 IU/day for 28 days in raising  $25(\text{OH})\text{D}$  values in their exclusively breastfed infants, and all infants achieved  $25(\text{OH})\text{D}$  concentrations  $>20$  ng/mL (50 nmol/L) [67]. Studies in a number of countries, including the United States, have documented poor adherence of caregivers to infant vitamin D supplementation [71–75]. Maternal supplementation with vitamin D to enrich their breast milk may be preferred to infant supplementation by some mothers, and it may avoid the potential for toxicity in the infant from dosing errors [76,77]; however, maternal supplementation to prevent vitamin D deficiency in the nursing infant cannot be recommended at present because of insufficient data on its safety or efficacy [78].

In the breastfed infant not receiving vitamin D supplements, the maintenance of an adequate vitamin D status is dependent mainly on the infant's exposure to ultraviolet light [79–81]. Specker and coworkers [79,80] have shown a marked seasonal variation in serum  $25(\text{OH})\text{D}$  concentrations in breastfed infants, which is influenced by the time spent outdoors and on the extent of skin exposed to sunlight. They have estimated that an infant in Cincinnati (latitude  $39^\circ 09' \text{N}$ ) requires to be outdoors for either 20 minutes a week in a diaper only or for 2 hours a week fully clothed but without a hat to maintain circulating concentrations of  $25(\text{OH})\text{D}$  above 11 ng/mL (27.5 nmol/L), which might by today's criteria not be considered optimal levels [79]. In a study conducted in Delhi ( $28.7^\circ \text{N}$ ), it was calculated that to achieve  $25(\text{OH})\text{D}$  of  $>20$  ng/mL (50 nmol/L) at 6 months of age, breastfed infants would be required to expose 40% of the body to 30 min weekly of sunshine (between 10 a.m. and 3 p.m.) for at least 16 weeks [82].

Seasonal variations in serum  $25(\text{OH})\text{D}$  concentrations have also been documented in a number of countries in older children and adults [83–85], and these variations appear to correlate with the amount of ultraviolet light reaching the earth [25]. These observations highlight the importance of the photo-biosynthesis of vitamin  $\text{D}_3$  in the skin to prevent vitamin D deficiency and thus rickets in many populations in the world [86]. In a number of countries such as Turkey [87], Saudi Arabia [58], India [88], Bangladesh [89], Iran [26], Kuwait [90], Kenya [91], Nigeria [92], Egypt [93], Ethiopia [94], and in others in the tropics and subtropics [95–99], rickets remains a problem despite generally good daily hours of sunshine. Several factors contribute to the persistence of the problem in these areas: overcrowding and poverty, atmospheric pollution [100], purdah, lack of access to sunlight, a lack of vitamin D–fortified foods or regular vitamin D supplements, and diets low in calcium and high in inhibitors of calcium absorption [101–106].

Despite its near eradication, the prevalence of nutritional rickets is increasing in high-income countries,

largely driven by an increased influx of immigrant and refugee children from parts of the world with a high prevalence of nutritional rickets [107–114]. Nutritional rickets is most frequent in children from the Middle East, Africa, and South Asia, even though many of these countries are located in the tropics with abundant sunshine [102–106]. Thus, there is now good evidence that nutritional rickets is a global public health problem, and not just the preserve of low- and middle-income countries (LMICs).

In the United States, despite the almost complete eradication of vitamin D deficiency among Caucasian children, several studies have highlighted the resurgence of the problem in specific groups [13,56,57,109,115–120], namely vegans and children on macrobiotic diets, children who are breastfed for prolonged periods, and African American children [120,121]. It is suggested that the combination of decreased vitamin D<sub>3</sub> formation in the dark skin, extensive skin coverage by clothing, low dietary vitamin D intakes because of the lack of intake of dairy products, and the generally low dietary calcium intakes associated with vegetarian diets contribute to an increased risk for nutritional rickets in these groups.

A similar pattern has also been documented in darker skinned immigrant populations in a number of European countries [108,110,122–125], North America [109,126], and Australia [107,127] and New Zealand

[128–130]. Since the initial descriptions of the resurgence of rickets in the United Kingdom in the early 1960s, numerous studies have been undertaken to determine why Asians are predisposed to the problem when other immigrants such as Afro-Caribbeans are thought to be less at risk [131]. Among the hypotheses put forward are simple vitamin D deficiency due to the dark skin and lack of skin surface exposed to sunlight [132,133], low calcium diets associated with vegetarianism [134], and impaired intestinal calcium absorption associated with high phytate diets [135]. A unifying hypothesis, proposed by Clements [136], suggests that in a situation of relative vitamin D insufficiency, the low dietary calcium and high phytate content of the typical Asian vegetarian diet leads to mild secondary hyperparathyroidism and a resultant increase in the catabolism of vitamin D. The progressive decline in vitamin D status culminates in the development of rickets.

The risk of nutritional rickets is a function of both vitamin D status and calcium intake [137]. Although rickets can result from either vitamin D deficiency or calcium deficiency, more commonly these two conditions interact to increase the risk of developing rickets (Fig. 63.1). The interaction of vitamin D and calcium to maintain bone mineralization is such that an adequate intake of either one will generally compensate for sub-optimal intake of the other. However, when both

calcium intake and vitamin D status are low, rickets can develop [138]. Vitamin D requirements are greater when dietary calcium intakes are low [137,139].

#### 4. Clinical presentation

Most clinical signs in children with rickets result from the effects of vitamin D deficiency on the mineralization process at the growth plate or on calcium homeostasis. Fraser and coworkers [43] described three stages in the progression of vitamin D deficiency. Stage I is characterized by hypocalcemia with clinical signs related to hypocalcemia. In stage II, the clinical features of impaired bone mineralization appear, and in stage III, signs of both hypocalcemia and severe rickets are present. This division of the progression of vitamin D deficiency rickets is conceptually useful, but there is considerable clinical overlap between the various stages.

The early clinical manifestations of vitamin D deficiency (stage I) related to hypocalcemia are seen most commonly in young infants (less than 6 months of age). They may present with convulsions [140,141], apneic episodes [142], tetany, cardiac failure, or even cardiac arrest [143], with no clinical signs of rickets. Children with symptomatic hypocalcemia are often not recognized to have vitamin D deficiency [144] despite even having radiologic evidence of rickets. In a population-based study of children aged 0–5 years in Olmsted County, Minnesota, the incidence of hypocalcemia with a potentially life-threatening complication was 6.1 per 100,000 person-years [144]. 25(OH)D was measured in only 3 of 16 children with symptomatic hypocalcemia [145]. Pseudotumor cerebri [146] and cataracts, probably due to hypocalcaemia, have also been reported in a young infant with rickets [147]. It has been suggested that symptomatic hypocalcemia in infants with vitamin D deficiency might be precipitated by an acute illness [148], during which there is a release of intracellular phosphate [149]. Why young infants are particularly predisposed to presenting in stage I is not clear, but it may relate to a delayed response of the parathyroid glands to hypocalcemia. In addition, these infants tend to have higher serum phosphate levels [150,151]; thus, the classical clinical and radiological features of rickets may not be evident during early infancy and at this stage of the disease.

Most children with vitamin D deficiency pass through the early phase of hypocalcemia asymptotically, presenting later with clinical features of rickets. Typically the infant or young child presents with a delay in motor milestones, hypotonia, irritability, and progressive deformities of the long bones. The deformities are most noticeable at the distal forearm with enlargement of the wrist and possible deformities of the distal radius

and ulna, and in the legs with progressive lateral bowing of the femur and tibia. The sites and types of deformity are dependent on the age of the child and the weight-bearing patterns in the limbs. Thus in the small infant, deformities of the forearms and anterior bowing of the distal tibias are more common, while in the toddler who has started to walk, an exaggeration of the normal physiological bowing of the legs (genu varum) is characteristic. In the older child, valgus deformities of the legs or a windswept deformity (valgus deformity of one leg and varus deformity of the other) may be apparent. The characteristic feature in the ribs is enlargement of the costochondral junctions, leading to visible beading along the anterolateral aspects of the chest (the rachitic rosary). Rachitic rosary was the most frequent clinical sign reported in children aged 6–18 months with rickets in Pakistan [152]. In the infant or young child with severe rickets, the muscular pull of the diaphragmatic attachments to the softened lower ribs results in the development of an Harrison sulcus (Fig. 63.2). The negative intrapleural pressure associated with breathing may result in narrowing of the lateral diameter of the chest (the violin case deformity) with consequent severe respiratory embarrassment. Increased sweating has also been described in young infants and probably relates to the increased work of breathing due to the decreased compliance associated with the excessively malleable ribs. In premature infants with rickets (which may also be due to dietary phosphorus deficiency), rib or forearm fractures may be the first clinical sign to draw attention to the problem [153].

Skull abnormalities associated with nutritional rickets include a delayed closure of the fontanelles, parietal and frontal bossing (hot-cross bun appearance), craniotabes [154], and craniosynostosis. Frontal bossing and widened fontanelles have been described as common features of breastfed infants with rickets in Pakistan [155]. Craniotabes is often considered to be highly suggestive of rickets if other causes such as hydrocephalus and osteogenesis imperfecta have been excluded. A number of studies have suggested craniotabes might be a normal finding in healthy young infants [156–158], although other studies in neonates have found an association with maternal vitamin D deficiency [159]. A large study in Japan showed the prevalence of craniotabes was affected by season of birth, and at 1 month of age, infants with craniotabes had a higher prevalence of elevated alkaline phosphatase concentrations, hyperparathyroidism, and low 25(OH)D levels [154]. Craniosynostosis, involving the coronal or multiple sutures, has been described in approximately 25% of children, who were followed up after having suffered from vitamin D deficiency rickets [145,160]. The development of craniosynostosis appears to be related to the degree of severity of the rickets and thus to the severity

**FIGURE 63.2** An infant with vitamin D deficiency rickets, presenting with respiratory distress. The child shows the characteristic deformities of the chest associated with severe rickets. The lateral diameter of the chest is reduced, and bilateral Harrison's sulci are present. The abdomen has a protuberant appearance. *Reproduced with permission from Ref. [240].*

of the mineralization defect, and inversely to the age of onset of the rickets.

A delay in tooth eruption is a feature of rickets in the young child, and enamel hypoplasia of teeth may occur if rickets develops prior to the completion of enamel deposition [161]. The latter has been reported in the primary dentition of infants born to mothers who are vitamin D deficient [162], and is seen in the secondary

dentition of children who have suffered from rickets during early childhood [161]. A number of studies have also found inverse associations between childhood vitamin D status and dental caries in childhood [163].

Hypotonia, decreased activity, and a protuberant abdomen are characteristic features of advanced vitamin D-deficient rickets in the infant and young child. These signs are probably analogous to the proximal muscle

weakness described in vitamin D–deficient adolescents and adults [164]. In this situation, deep tendon reflexes are retained and may be brisk. The pathogenesis of the myopathy is thought to be due primarily to vitamin D deficiency, rather than hypophosphatemia [165] (cf. Chapter 33—muscle).

Children with rickets typically have impaired growth and delayed motor milestones [130], which may be related to bone pain and muscle weakness. Although leg deformities can contribute to stunted height, restricted growth plate mineralization is probably a more important factor in limiting growth velocity in nutritional rickets [166]. Among the anthropometric parameters, height-for-age z-score is most severely reduced [167]. Nutritional rickets presents with general weakness, leg pain with walking or at rest, frequent falls, and inability to walk after infancy [167]. Five clinical features that were most predictive of active calcium deprivation rickets in Nigerian children were age <5 years, height-for-age less than 2 SD below the mean, leg pain during walking, wrist enlargement, and costochondral enlargement [168].

A child may have bone deformities characteristic of rickets, but radiographs do not show active rickets and biochemical abnormalities. Such children may have had active rickets earlier that has healed spontaneously, if the child has been able to catch up with the demands for calcium and vitamin D. Bone deformities were found in 3.3% of children clinically screened for rickets in The Gambia, but only 9% of those with deformity had active rickets on X-ray [169]. Among Nigerian children over age 18 months presenting with bone deformities, 38% had radiographically active rickets [168]. Radiographic confirmation is essential to determine if rickets is active.

Dilated cardiomyopathy and cardiac failure [170,171] have also been described in young infants with vitamin D deficiency and have been described as one of most serious complications of vitamin D deficiency [172]. Infants can present either with rickets or dilated cardiomyopathy as the initial diagnosis [171,173]. If a holistic approach to the investigations and management of these children is not adopted, then either of these two pathologies can be missed when presenting concurrently. In one series of the 18 infants diagnosed with vitamin D deficiency and cardiomyopathy, eight were ventilated and three died, indicating the severity of this complication in young infants [174]. The mechanism is thought to be due to the effect of hypocalcemia on cardiac muscle function, rather than a direct effect of hypovitaminosis D [175]. These abnormalities returned to normal after treating the rickets [175].

Infants and young children with rickets are prone to an increased number and severity of infections [176,177]. The prevalence of nutritional rickets among children under age 5 years in Uganda with severe

pneumonia was 9.5% [178]. Although the increase in respiratory infections may be explained on the thoracic cage abnormalities (softening of the ribs, the enlarged costochondral junctions, and the decreased thoracic movement due to muscle weakness), the now well-documented role of 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ) in modulating immune function [179–181] may contribute to the observed increase in infections. Impaired phagocytosis [182] and neutrophil motility [183] have been described in children with vitamin D deficiency rickets, and the lack of production of cathelicidin following the activation of Toll-like receptors may play a role in predisposing vitamin D–deficient subjects to *Mycobacterium tuberculosis* infection [184].

A possibly associated abnormality is anemia, thrombocytopenia, leukocytosis, myelocytosis, erythroblastosis, myelofibrosis [185], myeloid metaplasia, and hepatosplenomegaly (von Jaksch–Luzet syndrome) [186], which has been described in infants with rickets [187]. Although the exact pathogenetic mechanisms for this syndrome are unclear, vitamin D deficiency has been implicated based on the clinical observation that vitamin D therapy cures the condition and on experimental evidence showing that  $1,25(\text{OH})_2\text{D}$  has antiproliferative activity on myeloid leukemia cell lines [188].

## 5. Biochemical abnormalities

The hallmark of vitamin D deficiency is a low circulating level of  $25(\text{OH})\text{D}$ . In healthy children and adults, a range of approximately 12.5–50 ng/mL (30–125 nmol/L) has been found in the majority of studies [84,189–191] conducted in communities in which vitamin D–deficient rickets is uncommon. However, the normal range is dependent not only on the vitamin D and calcium contents of the diet and on the ultraviolet light exposure of the skin, but also on the definition of vitamin D deficiency. In a number of studies, a marked seasonal variation in levels has been recorded [83,84,192], reflecting in part the seasonal changes in the amount of ultraviolet light reaching the earth. During the winter months, at latitudes above 40°N or S, insufficient UV radiation reaches the earth to allow any cutaneous synthesis of vitamin D [25,193]. In countries at high latitude where foods are not vitamin D fortified, serum  $25(\text{OH})\text{D}$  concentrations in some “normal” children may be in the range documented in symptomatic children with vitamin D deficiency [83,194]. Thus the development of symptoms depends on the duration and severity of low  $25(\text{OH})\text{D}$  concentrations and on the ability of the kidney to achieve adequate  $1,25(\text{OH})_2\text{D}$  concentrations in the face of decreased substrate for the gastrointestinal tract to maintain calcium absorption at a level appropriate to meet the

demands of the growing child. In children with 25(OH)D concentrations within the normal reference range, there is no correlation between serum 25(OH)D and 1,25(OH)<sub>2</sub>D concentrations. However, once 25(OH)D levels fall below ~12 ng/mL (30 nmol/L) 1,25(OH)<sub>2</sub>D concentrations correlate with those of 25(OH)D [195–197]. In the majority of studies in which 25(OH)D values have been measured in children with vitamin D deficiency rickets, concentrations have been found to be less than 4–5 ng/mL (10–12.5 nmol/L) in most patients [40,194,198], although other researchers have found higher values [199–201].

The classical biochemical changes in vitamin D-deficient children who have radiological changes of rickets are a combination of hypocalcemia, hypophosphatemia, and elevated alkaline phosphatase and parathyroid hormone (PTH) concentrations. Over 50 years ago, Fraser and coworkers [39] elegantly described the biochemical progression in children with rickets as vitamin D deficiency became more severe and prolonged. In the early phase of vitamin D deficiency before the development of radiological signs (stage I), hypocalcemia may be the only biochemical abnormality [43]. Acute illness may precipitate hypocalcemia in the vitamin D-depleted infant through the sudden increase in serum phosphorus concentrations [149]. The biochemical picture is such that stage I rickets may be confused with that of hypoparathyroidism or pseudohypoparathyroidism [202], as hypocalcemia, hyperphosphatemia, and normal alkaline phosphatase levels may also be found [203]. As vitamin D deficiency progresses, secondary hyperparathyroidism in response to the hypocalcemia induces a partial correction of the low serum calcium concentration, which may return to levels within the normal range, and increases phosphate excretion by the kidney resulting in hypophosphatemia (stage II) [204]. At this stage, serum alkaline phosphatase concentrations are usually elevated, and other renal manifestations of secondary hyperparathyroidism, such as increased cyclic AMP excretion, generalized aminoaciduria, impaired acid excretion, and decreased urinary calcium excretion, are found [205]. In stage III of the disease, the radiological features are more severe, hypocalcemia once again becomes apparent, and alkaline phosphatase concentrations rise further [43]. Evidence of end-organ resistance to PTH has been found in young children with both mild and more severe radiological rickets [206,207]. In a study by Kruse [206], children with mild rickets remained normophosphatemic and had normal renal handling of phosphate (TmP/GFR) despite elevated PTH concentrations and increased urinary cyclic AMP excretion. Similar indirect evidence of PTH resistance (hypocalcemia, normophosphatemia, and a decrease in the renal phosphate excretion index) was noted by Taitz [207] in infants with more severe

radiologic rickets. Resistance to PTH has also been described in hypocalcemic adolescents with mild rickets [208]. Usually, however, as the severity of the rickets increases (stages II and III), PTH values rise further, and renal hyporesponsiveness is overcome [206]. Thus, hypophosphatemia and a decrease in TmP/GFR become hallmarks of the disease.

## 6. Biomarkers of active rickets

Urine calcium to creatinine ratios were found to be very low in rachitic Nigerian children and lower than in control children without rickets [167]. However, neither the urine calcium to creatinine ratio nor urine phosphorus was related to serum 25(OH)D in US children without nutritional rickets, and the investigators concluded that urinary calcium and phosphorus were not useful screening tests for vitamin D deficiency [209].

Markers of bone turnover are typically elevated in nutritional rickets in response to the development of secondary hyperparathyroidism. Urinary hydroxyproline excretion may be within the normal range in stage I rickets, but is elevated in patients with radiologic rickets [206], and an increase in serum concentrations of bone resorption markers has been reported in children with untreated rickets [210,211] and in those with asymptomatic vitamin D deficiency [212]. Similarly, serum alkaline phosphatase values may be normal in stage I of vitamin D deficiency, but rise with the degree of severity of the radiologic changes. On treatment, bone turnover markers (especially those of bone resorption) rise in the first 2–3 weeks and then fall progressively to normal values over a period of 4–6 weeks [211]. Of all the readily available biochemical tests that might be deranged in nutritional rickets, alkaline phosphatase has been used most frequently as a screening test. However, although it is elevated in nearly all children with radiological changes, it lacks specificity, and normal values vary with age [213]. Serum alkaline phosphatase levels are generally related to the radiological severity of rickets [95,214]. Although cholestatic liver disease is associated with vitamin D deficiency and elevated liver alkaline phosphatase, bone specific alkaline phosphatase [215] is generally not required to identify the source of elevated alkaline phosphatase, if radiological changes confirm the diagnosis of rickets and values improve with treatment. Elevated alkaline phosphatase effectively discriminated between Nigerian children with and without nutritional rickets [216]. Alkaline phosphatase is a low-cost biochemical test that could be used to screen for nutritional rickets, but cutoff values require validation in other populations, and laboratory values need to be standardized for widespread population studies [216].

In a small study of rachitic subjects, the authors suggested that the measurement of deoxypyridinoline in a first morning void urine sample might be a useful indicator of rickets, values being significantly higher in patients than in age matched controls [217]. In a case–control study of urinary biomarkers in children with and without nutritional rickets in China, the combination of urinary phosphate and sebacic acid had high sensitivity (94.0%) and specificity (71.2%) for nutritional rickets [218].

Osteocalcin is a noncollagenous bone matrix protein that binds to hydroxyapatite and is secreted by osteoblasts during mineralization [219]. Serum concentrations are higher in children than adults and peak during the pubertal growth spurt [220]. In the few children with untreated vitamin D deficiency rickets, in whom serum osteocalcin concentrations have been measured, values have been reported to be low [211] or normal [221], and may rise rapidly on therapy to supranormal concentrations [222]. One Nigerian study [210] of 12 rachitic children found slightly elevated serum osteocalcin concentrations compared with values in age-matched controls, while another found levels to be similar or slightly lower in rachitic children than controls [223]. The children in both these studies had low dietary calcium intakes.

In patients with vitamin D deficiency, serum  $1,25(\text{OH})_2\text{D}$  concentrations have been reported to be low, normal, or even elevated [195,198,201,206,224,225], while  $24,25(\text{OH})_2\text{D}$  values are low or undetectable [195,198,201,224,226]. Kruse [206] found that  $1,25(\text{OH})_2\text{D}$  values were higher in children with stage II rickets than in those with either stage I or stage III rickets. The finding of normal or elevated levels of  $1,25(\text{OH})_2\text{D}$  in vitamin D deficiency rickets has led some researchers to conclude that other vitamin D metabolites, such as  $24,25(\text{OH})_2\text{D}$ , are necessary for the maintenance of normal calcium homeostasis [225,227,228], but the evidence for this is not convincing. Others have suggested that although concentrations are within the normal range, they are inappropriately low for the degrees of hypocalcemia and hyperparathyroidism [206,224]. As discussed later, the latter hypothesis is more likely.

One indicator of relative or functional vitamin D deficiency that has been observed in nutritional rickets is a rapid rise in  $1,25(\text{OH})_2\text{D}$  levels in response to vitamin D administration [229]. This has been interpreted as a response to vitamin D administration in a situation of a relative lack of substrate  $25(\text{OH})\text{D}$  in the presence of PTH stimulation of renal  $1\alpha$ -hydroxylase.

Circulating concentrations of IGF-1 in children with nutritional rickets were positively correlated with  $25(\text{OH})\text{D}$  and increased significantly after treatment of rickets with vitamin D [166]. Growth velocity after

treatment of active rickets was related to the increase in IGF-1 and  $25(\text{OH})\text{D}$  levels, suggesting that accelerated linear growth after treatment of nutritional rickets may be mediated by IGF-1 secretion.

The possible pathophysiological progression of vitamin D deficiency rickets in children may be described as follows [206,230]. As the child becomes progressively vitamin D depleted, a stage is reached when the serum  $25(\text{OH})\text{D}$  concentration falls below that required to maintain a serum  $1,25(\text{OH})_2\text{D}$  level necessary to ensure the required intestinal calcium absorption for normal calcium homeostasis. The resultant hypocalcemia (stage I rickets) leads to secondary hyperparathyroidism, which, through the stimulation of  $1\alpha$ -hydroxylase (CYP27B1), increases  $1,25(\text{OH})_2\text{D}$  production despite falling  $25(\text{OH})\text{D}$  concentrations. In concert with PTH,  $1,25(\text{OH})_2\text{D}$  increases bone resorption and intestinal calcium absorption, thus returning serum calcium concentrations toward normal (stage II rickets). The presence of hypophosphatemia at this stage is probably responsible for the mineralization defect and the development of radiologic rickets.

It is during stage II that serum  $1,25(\text{OH})_2\text{D}$  concentrations may be elevated [206]. A possible explanation for the failure of the elevated  $1,25(\text{OH})_2\text{D}$  levels to reduce the hyperparathyroidism and heal the bone disease at this stage is that the concentrations are not high enough to meet the increased calcium requirements associated with the generalized mineralization defect and increased bone turnover. Support for this hypothesis comes from data, which show that  $1,25(\text{OH})_2\text{D}$  concentrations rise to considerably higher levels (3–5 times normal) during the healing process even when only small doses of vitamin D are provided [195,206] and that intestinal calcium absorption may reach ~80% of dietary calcium intake during this phase [195,231]. The hyperparathyroidism can lead to a further decrease in  $25(\text{OH})\text{D}$  concentrations through both increased conversion to  $1,25(\text{OH})_2\text{D}$  by CYP27B1 and increased degradation by  $24$ -hydroxylase (CYP24A1), induced by  $1,25(\text{OH})_2\text{D}$  [232,233].

As  $25(\text{OH})\text{D}$  concentrations fall further,  $1,25(\text{OH})_2\text{D}$  levels once again fall, despite persistent hyperparathyroidism, because of the lack of substrate. However, this does not typically occur in adults unless the  $25(\text{OH})\text{D}$  concentrations fall below 10 nmol/L (4 ng/mL) [234]. Hypocalcemia again becomes apparent as intestinal calcium absorption falls and calcium mobilization from bone decreases due to the extent of unmineralized osteoid covering bone surfaces and the lack of  $1,25(\text{OH})_2\text{D}$ , which has a permissive action on bone resorption by PTH [235,236]. The combination of both hypocalcemia and hypophosphatemia increases the severity of the bone disease (stage III).

## 7. Radiologic changes

The typical radiologic changes associated with nutritional rickets have been well described and are discussed in Chapter 54—radiology. Radiographic features of rickets reflect disordered mineralization and ossification of the growth plate [237]. Stage I rickets characteristically shows few radiologic signs, although diffuse demineralization caused by secondary hyperparathyroidism might precede the changes at the growth plate [237]. The changes of rickets are best visualized at the growth plate of rapidly growing bones. Thus, in the upper limbs, the distal ulna may show best the early signs of impaired mineralization [238]. In the older child, the metaphyses round the knees become more useful. Other radiologic findings include fractures, periosteal new bone, and bowing deformities [237].

The early signs of rickets include widening of the physal plates and a loss of definition of the provisional zone of calcification at the metaphyses [239]. As the disease progresses, the disorganization of the growth plate becomes more apparent with cupping, splaying, spur formation, and stippling [149,240] (Fig. 63.3). The appearance of epiphyses may be delayed, or they appear small, osteopenic, and ill-defined.

As noted before, not all children with rachitic-like bone deformities have active rickets at the growth plates. In Nigerian children, an age below 5 years, height-for-age Z-score less than 2, leg pain during

walking, wrist enlargement, and costochondral enlargement were independently predictive of active rickets on radiographs [168]. Any three of these clinical features accurately identified 87% of children with active rickets. Among children in Pakistan, 2–36 months old, with clinical signs of rickets and elevated alkaline phosphatase, radiological findings suggestive of rickets were found in 54% [152].

A widely used radiographic severity score (RSS) has proven useful to quantify the severity of radiographic changes of rickets, based on wrist and knee radiographs [169,214,241–243]. The score ranges from 0 to 10, where 10 represents the most severe rickets. The RSS correlates well with serum alkaline phosphatase values. The RSS has been independently validated in low-income and high-income countries, and it is particularly useful for clinical trials involving children with rickets to numerically measure the severity of rickets [46,238,244]. The RSS was independently validated in children with rickets in India, and the distal ulna was the last to heal in most cases [238]. These investigators concluded that the distal ulna could be used for diagnosis and follow-up in nutritional rickets, except in severe cases, where the distal femur was a better radiological indicator. They derived a linear regression formula to predict the expected time for radiological resolution, based on RSS. Along with the RSS, a radiographic global impression of change (RGI-C) score has been used to assess improvement in genetic forms of rickets, such as

**FIGURE 63.3** The radiographic features of vitamin D deficiency rickets at the wrist. *Left panel:* untreated vitamin D deficiency showing underdevelopment of the epiphyses, widening of the physal plates, splaying and irregularity of the metaphyses, and loss of the provisional zone of calcification. The shafts of the radius and ulna show coarsening of the trabecular pattern and loss of the normal cortical definition. *Middle panel:* response after 3 months of vitamin D therapy. The metaphyses show clear signs of healing with dense bands of calcification at the distal ends of the metaphyses, narrowing of the physal plates, and more clearly defined epiphyses. The trabecular pattern still appears coarse but shows improvement. *Right panel:* six months after starting vitamin D therapy. The radiographic changes of rickets have disappeared. The epiphyses, physal plates, metaphyses, and trabecular structure are normal. *Reproduced with permission from Ref. [240].*

hypophosphatasia and X-linked hypophosphatemic rickets [245,246]. The RGI-C could also prove applicable to assess healing in studies of nutritional rickets. An artificial intelligence object detection model has reasonable sensitivity and specificity to identify rickets on pediatric wrist radiographs [247].

The shafts of the long bones show features of both hyperparathyroidism and osteomalacia. Osteopenia is a characteristic feature, which in the so-called “atrophic” form of the disease may be very severe [95]. The cortices become thin and may show periosteal new bone formation, although this is more frequently seen during healing. The trabecular pattern is reduced and appears coarse. Deformities of the shafts of the long bones are typically present, and in severe rickets, pathological fractures and Looser zones may be noted. In vitamin D-deficient rickets, features of hyperparathyroidism, such as subperiosteal erosions, are uncommon. However, loss of the lamina dura around the teeth is frequently seen.

Enlargement and splaying of the costochondral junctions on the lateral radiographs of the chest have been used as a sign of rickets; however, in one study, mild changes were found to be unreliable as their presence did not correlate with serum 25(OH)D concentrations or with other features of rickets at the distal radius and ulna [248].

Rickets during adolescence may be difficult to detect using the conventional radiographic sites of the wrist and knees as the epiphyseal plates narrow and epiphyses fuse. A radiograph of the pelvis may be useful in this situation as the secondary iliac and ischial ossification centers (apophyses) may be abnormally wide [249]. These centers appear at puberty and normally unite with the rest of the bone between the 15th and 25th years of age.

The earliest sign of healing of rickets is the appearance of broadened bands of increased density corresponding to the zone of provisional calcification in the distal metaphysis, often apparent within 6 weeks of treatment [250] (Fig. 63.3). The demarcation of the broad bands on the diaphyseal side of the shaft may be poorly defined [239]. Healing in more severe cases of rickets may first appear as bands of mineralization occurring distal to and separated from the irregular and frayed metaphyses. There is then gradual filling in of the demineralized area on the diaphyseal side of the initial band of mineralization with remodeling and the development of a normal trabecular pattern. Periosteal new bone formation may be seen, which gradually becomes incorporated into the cortices of the long bones.

The radiographic features of child abuse can sometimes be confused with nutritional rickets. The classic metaphyseal fractures of child abuse are “bucket handle” linear densities or triangular “corner fractures” from the lateral aspect of the metaphysis, which generally do not occur in rickets [251]. Fractures were present

in 17.5% of 45 US children under age 24 months with rickets and exclusively found in mobile infants and toddlers [252].

Measurement of bone density is not generally indicated for the evaluation of nutritional rickets. Nutritional rickets results in increased forearm bone area and reduced areal bone mineral density (BMD), which are more pronounced in the diaphyseal than in the metaphyseal regions of the radius and ulna, consistent with secondary hyperparathyroidism, generalized osteoid expansion, and impaired mineralization [253]. Nutritional rickets in Nigerian children was not associated with maternal forearm areal BMD [254]. After treatment of rickets, diaphyseal areal BMD z-scores did not differ between children with treated rickets and control children without rickets [255]. However, metaphyseal areal BMD z-scores were greater in children with treated rickets than in control children without rickets.

## 8. The growth plate in rickets

The characteristic feature in all forms of rickets is the abnormality that occur at the growth plate or physis. The cartilaginous plate consists of resting, proliferating, and hypertrophic zones of chondrocytes, and in rickets, it is the hypertrophic zone that is affected through widening and loss of organization of this zone. The widening is caused by marked impairment of apoptosis of the hypertrophied cells through an inhibition of the caspase-9-mediated mitochondrial pathway [256]. It appears that in all forms of rickets, the inhibition of apoptosis is as a consequence of hypophosphatemia, rather than through a direct effect of vitamin D or one of its metabolites [257,258]. Studies suggest that the sodium-dependent phosphate cotransporter (NaPi-IIc) is intimately involved as a phosphate transporter in hypertrophied chondrocytes [258], and thus as a regulator of apoptosis. The widening of the hypertrophic zone of the growth plate due to impaired apoptosis can be reversed or prevented by correcting the hypophosphatemia without altering the basic defect causing the rickets [256] (e.g., without altering PHEX or FGF23 in X-linked hypophosphatemia, or without correcting the VDR abnormalities in hereditary vitamin D-resistant rickets). However, correction of the hypophosphatemia does not correct the subgrowth plate metaphyseal changes of rickets, which manifest with impaired vascular invasion and reduced osteoclast numbers.

## 9. Treatment

Vitamin D-deficient rickets can be effectively treated by the oral administration of small doses of either

**TABLE 63.1** Recommended vitamin D<sub>3</sub> doses for the treatment of vitamin D deficiency in children of different ages.

Age	Daily dose for 90 days, IU	Single dose, IU	Maintenance daily dose, IU
<3 months	2000	N/A	400
3–12 months	2000	50,000	400
>12 months to 12 year	3000–6000	150,000	600
>12 year	6000	300,000	600

N/A, not available. Reassess response to treatment after 3 months as further treatment may be required. Ensure a daily calcium intake of at least 500 mg. For conversion from IU to µg, divide by 40.

Reproduced with permission from Ref. [22].

vitamin D<sub>2</sub> or D<sub>3</sub>, provided there is no evidence of gastrointestinal malabsorption. Stanbury et al. [195] showed that an oral vitamin D dose of between 200 and 450 IU/day produced a rise in serum 1,25(OH)<sub>2</sub>D concentrations to normal values within 1–3 days. The latter climbed to reach a peak some five times the normal mean after 1–3 weeks, despite serum 25(OH)D values remaining less than 10 ng/mL (25 nmol/L). Similarly, spontaneous improvement in the biochemical features of rickets has been reported to occur in children with biochemical abnormalities during the summer months, associated with a rise in serum 25(OH)D values due presumably to increased ultraviolet light exposure [259].

As per the Global Consensus guidelines on nutritional rickets, the recommended dose of cholecalciferol is 2000 IU/day in patients less than 1 year of age, 3000–6000 IU/day in patients aged 1–12 years, and 6000 IU/day in patients older than 12 years for 3 months (Table 63.1) [22]. A single large oral dose has also been used successfully, especially when caregiver adherence to the daily dose may be problematic.

Normalization of serum calcium and phosphorus concentrations occurs within 1 and 3 weeks [206], although serum alkaline phosphatase concentrations and urinary hydroxyproline excretion remain elevated for several months. Despite the return to normal of serum PTH, calcium, and phosphorus values within 3 weeks, serum 1,25(OH)<sub>2</sub>D concentrations may remain elevated for up to 10 weeks [201,206]. Serum 24,24(OH)<sub>2</sub>D values, which are often undetectable in the untreated patient, rise with the progressive increase in serum 25(OH)D concentrations during treatment [201]. Lower doses of vitamin D (1000–2000 IU/day) do produce healing, but the response is less rapid.

A randomized clinical trial found that daily vitamin D<sub>2</sub> or D<sub>3</sub> (2000 IU) was as effective as weekly vitamin D<sub>2</sub> (50,000 IU) over a 6-week period in correcting hypovitaminosis D in young children [260]. The authors concluded that the option of daily or weekly treatment may help to individualize treatment to suit parental needs and thus reduce the likelihood of noncompliance,

which has been reported to be a common problem especially when vitamin D supplementation is used long-term for the prevention of hypovitaminosis D. The study also clearly showed the equivalence of vitamin D<sub>2</sub> and D<sub>3</sub> in the treatment of hypovitaminosis D, a finding confirmed by Holick and coworkers, who measured serum 25(OH)D concentrations and found similar values in the D<sub>2</sub>- and D<sub>3</sub>-treated groups in adult subjects treated with either vitamin D<sub>2</sub> or D<sub>3</sub> at daily doses of 500 IU or 1000 IU over an 11-week period [261]. This equivalence may not hold when vitamin D is given in intermittent large doses as vitamin D<sub>2</sub> has a reduced half-life compared with vitamin D<sub>3</sub>.

In Central Europe, a single dose of 600,000 IU vitamin D (either orally or intramuscularly) has been found to be effective in treating vitamin D-deficient rickets, resulting in a rapid improvement in biochemical abnormalities within a few days and radiologic evidence of healing within 2 weeks [15,262]. Similarly, single-dose treatment with 600,000 IU has been used to treat rickets in the United States and India [262,263]. A sustained drop in serum alkaline phosphatase is seen within 6–12 weeks [262]. Single-dose therapy has an advantage over smaller daily doses as it avoids the problem of compliance, which was thought to be responsible for the lack of response in 40% of children with vitamin D-deficient rickets in a study conducted in Kuwait [264]. Concern has been raised about the use of 600,000 IU vitamin D in the treatment of rickets as hypercalcemia has been reported in a small number of infants a month after having received the vitamin D dose [265,266]. These authors suggest that a dose of 150,000 IU is equally effective as the larger dose in the management of the disease without running the risk of hypercalcemia. In a study conducted in Pakistan, the authors compared the efficacy of using either intramuscular or oral vitamin D<sub>3</sub> (200,000 IU as a single dose) for the treatment of active rickets in young children. No difference in response rate, which was very good, was noted between the two groups; however, the parents preferred the intramuscular treatment [267]. A single intramuscular dose of

vitamin D<sub>3</sub> (10,000 IU/kg body weight) has also been reported to be effective and safe in treating rickets in children [268]. 25(OH)D concentrations were above 20 ng/mL (50 nmol/L) in all but 12.5% of the subjects 3 months after the injection.

Besides ensuring an adequate vitamin D intake, the calcium content of the diet should be optimized (between 500 and 1000 mg/day). This is particularly true for children who are on vegetarian or low calcium-containing diets [269] and for those who are severely hypocalcemic. In symptomatic patients, a single dose of calcium gluconate (1–2 mL/kg of a 10% solution) may be given slowly intravenously and the diet supplemented with 10% calcium gluconate (5 mL/kg/day in divided doses). Oral calcium of 500 mg/day regardless of age or weight is recommended to prevent “hungry-bone syndrome” [22]. The combination of vitamin D and calcium in the treatment of nutritional rickets led to more rapid improvement in radiographic severity and alkaline phosphatase than either vitamin D or calcium alone [270,271].

Surgical correction of persistent leg deformities may be required in older children or in those with severe bone deformities. Most deformities of rickets correct spontaneously after medical treatment, without bracing or surgical intervention. In Indian children, the average rate of spontaneous correction was 1.9°/month with varus deformity and 0.92°/month with valgus deformity [272]. These investigators observed that varus deformities in children over the age of 4 years and 18° or greater valgus deformity in children over the age of 9 years usually do not correct spontaneously and may require surgical intervention. In Egyptian children with rickets treated with femoral and/or tibial temporary hemiepiphysiodesis at a mean age of 3.8 years, the mean time for resolution of deformity was 1.5 years [273]. Surgery was recommended for persistent or progressive tibiofemoral angle greater than 20° over 6 months.

## 10. Prevention

Vitamin D-deficient rickets remains a problem in at-risk groups despite readily available methods of preventing the disease. Prospective studies have assessed vitamin D status in breastfed infants in multiple countries. Several have shown a fall in serum 25(OH)D concentrations in those infants who were not vitamin D supplemented, to levels in the vitamin D deficient range [30,274,275], although this was not a universal finding [276,277]. Further, a number of studies have highlighted the high prevalence of vitamin D deficiency in mothers during pregnancy and lactation, which exacerbates the severity and onset of vitamin D deficiency in their offspring [278–281]. In a number of countries, a further

group that probably does not receive enough attention is the adolescent, as the prevalence of vitamin D deficiency tends to rise in this age group [282,283]. In the United States, adolescent vitamin D deficiency is particularly prevalent in African American teenagers, in the overweight, and in females [284].

Thus, preventive strategies should be directed not only at breastfed infants but also at pregnant and breastfeeding women and adolescents where appropriate [285]. North America [19] recommends dietary intakes of vitamin D between 600 and 1200 IU/day for pregnant and lactating women, respectively, to ensure adequate circulating 25(OH)D levels. In 2016, the Scientific Advisory Committee on Nutrition in the United Kingdom [286] did not recommend an increased vitamin D intake in pregnant and lactating women over and above the standard 400 IU/day to maintain 25(OH)D > 25 nmol/L. Yet, studies have shown that these recommended intakes may not be adequate to maintain 25(OH)D concentrations in the sufficiency range [68,287–289], and some researchers suggest that intakes of 1000–2000 IU/day are more appropriate [290].

Although at normal circulating maternal 25(OH)D concentrations, the vitamin D content of breast milk is limited, maternal supplementation with vitamin D at 4000–6400 IU/day increases breast milk vitamin D concentrations sufficiently to maintain the infant's 25(OH)D within the normal range [67,291]. Most breastfeeding mothers in a US practice preferred supplementing themselves rather than their infants, and most preferred daily rather than monthly supplementation [292]. Safety was most important to mothers in choosing a method of supplementation. Taking maternal preferences into consideration for infant or maternal vitamin D supplementation may help to ensure adequate intakes of vitamin D in breastfed infants. Potential advantages of maternal over infant supplementation include ease of administration, simultaneous mother and infant supplementation, and lower risk of toxicity to the infant from dosing errors. Oral vitamin D 120,000 IU monthly given to lactating mothers in India achieved 25(OH)D > 20 ng/mL in 95% of infants [293]. Monthly maternal supplementation could be incorporated in established mother/child visits for prevention of nutritional rickets.

North America and the United Kingdom recommend vitamin D dietary intakes of 400 and 340–400 IU, respectively, for the breastfed infant [19,286]. The Global Consensus Guidelines for the Prevention of Rickets recommended that all infants, irrespective of feeding methods, receive daily vitamin D of at least 400 IU for the first 12 months of life, and 600 IU should be given to pregnant women, toddlers, and children at high risk of vitamin D deficiency and rickets [22]. The American Academy of Pediatrics advises that infants less than 6 months of age should be kept out of direct sunlight,

that children's activities should minimize sunlight exposure, and that sunscreens should be used, because of the indirect evidence that early exposure to sunlight might determine the risk of skin cancer in later life [294]. These recommendations make it imperative that if the aforementioned guidelines are followed, supplemental vitamin D (400 IU/day) should be provided to all breastfed and weaned infants ingesting less than 500 mL of fortified infant milk formula/day [295–298]. In a prospective study conducted in China on infants from birth to 6 months of age, supplemental vitamin D at a dose of 400 IU/day produced more normal circulating 25(OH)D concentrations than did either 100 or 200 IU/day [299]. However, in a small number of infants, even 400 IU/day did not maintain 25(OH)D levels above 11 ng/mL (27.5 nmol/L). Nevertheless, no radiologic evidence of rickets was found in any of the infants in the three groups at 6 months of age [87,300]. Although 400 IU/day of vitamin D prevents rickets and maintains a normal vitamin D status in the majority of infants [301], higher intakes may be required to reduce the prevalence of type 1 diabetes in children [302].

Infants who are fed milk formulas or cow's milk fortified with vitamin D and drink more than 1000 mL/day do not require vitamin D supplements, as their intake of milk generally provides sufficient vitamin D to prevent deficiency [294]. The recent consensus statement [22] does not differentiate between breastfed and artificially fed infants, as no harmful effects of the additional vitamin D intake in artificially fed infants have been reported.

High single dose therapy (stosstherapie) has been used with success in the treatment of vitamin D-deficient rickets in a number of countries. A similar dosing strategy has also been used on a regular intermittent basis of every 3–5 months for the first 18 months of life for prevention of vitamin D deficiency. In a study assessing the effect of high doses of vitamin D (600,000 IU) on calcium and vitamin D metabolism in infants [15], serum 25(OH)D concentrations reached very high levels 2 weeks after each administration, but these had returned to normal prior to the next dose. 1,25(OH)<sub>2</sub>D generally remained within the normal range; however, 34% of infants were hypercalcemic at some stage during the study. These results led the authors to conclude that the dosage regimen as used during the study was excessive and unsafe [15]. However, a study, using the same dose (600,000 IU intramuscularly) annually in adults for the management of vitamin D deficiency, reported that at the end of 12 months, serum 25(OH)D concentrations were still in the optimal range and that the treatment appeared safe, although further studies are required to examine urine calcium excretion and the risk of hypercalcemia in a larger group of subjects [303].

Following on these results, a study to assess the efficacy of a single dose of vitamin D (600,000 IU or 15 mg) at 15 days of life, compared with 200,000 IU (5 mg) or 100,000 IU (2.5 mg) at birth and three monthly for 9 months, has been undertaken [304]. Two weeks after the initial administration, 28 of 30 infants in the 15 mg group had serum 25(OH)D concentrations above the upper limit of normal (mean  $\pm$  SD for the group;  $307 \pm 160$  nmol/L) compared with 58% ( $150 \pm 55$  nmol/L) in the 5 mg group and 23% ( $92 \pm 42$  nmol/L) in the 2.5 mg group. At 6 months of age, 50% of the infants who had received 15 mg at birth still had elevated 25(OH)D concentrations (defined in this study as being  $>120$  nmol/L), while in the 5 mg group, none had elevated levels. In the group receiving 2.5 mg three monthly, serum 25(OH)D values were in the normal range on each occasion prior to receiving the next dose. Although hypercalcemia was not detected in any of the infants, serum calcium concentrations were higher in the 15 mg group 2 weeks after receiving the dose than in the other two groups. The authors concluded that intermittent doses of 15 mg vitamin D during the first year of life are excessive and that 5 mg every 6 months or even better 2.5 mg every 3 months are more suitable for the prevention of vitamin D deficiency in at-risk infants.

The same group of researchers studied the use of intermittent vitamin D supplementation to prevent vitamin D deficiency during the winter months in adolescents in northern France [305]. They recommend a single dose of 100,000 IU in early autumn, midwinter, and again at the beginning of spring to maintain 25(OH)D concentrations above 20 ng/mL. On this regimen, the usual winter rise in PTH and fall in vitamin D status were prevented. However, in a well-designed randomized controlled trial of vitamin D<sub>3</sub> 100,000 IU orally every 3 months for 18 months in infants in Afghanistan, the prevalence of rickets was similar in the vitamin D and control groups at the end of the study (5.3% vs. 5.5%, respectively) [306]. Height-for-age z-scores were also similar between the two groups at the end of the study. Concern with high-dose intermittent therapy has been raised, related to the observation that a single high dose of vitamin D can induce 24-hydroxylase (CYP24A1), resulting in greater catabolism of 25(OH)D through increased production of 24,25(OH)<sub>2</sub>D relative to 1,25(OH)<sub>2</sub>D compared with that seen during daily supplementation [181,307,308].

Vitamin D supplementation should be considered for all infants until they are ambulatory and are able to play outside [309]. Even in countries close to the equator, where sunlight exposure should not be a problem, social customs may place the mother and infant at risk from vitamin D deficiency. In such situations (e.g., the Middle East and in Muslim communities in North Africa and

the Asian subcontinent), vitamin D supplementation may also be necessary to reduce the high prevalence of vitamin D deficiency [279,310].

In some countries, vitamin D deficiency is not just a finding in breastfed infants and their mothers. Rickets has been described in adolescents of Indian and Pakistani descent in the United Kingdom and in the Middle East [311,312], while hypovitaminosis D has been reported in adolescents in a number of European countries [313–316], India [317,318], and China [319]. To address this problem, Fuleihan and her coworkers have studied the use of weekly therapy over 1 year in adolescent schoolchildren [320]. Vitamin D<sub>3</sub> 14,000 IU weekly produced mean serum 25(OH)D concentrations in the mid-30s (ng/mL), while a dose 10 times smaller (1400 IU weekly) did not raise the mean above 20 ng/mL (50 nmol/L) in the female subjects. They concluded that a vitamin D dose of 14,000 IU/week (equivalent of 2000 IU/day) was safe and effective in ensuring vitamin D sufficiency in an adolescent population at risk of vitamin D deficiency.

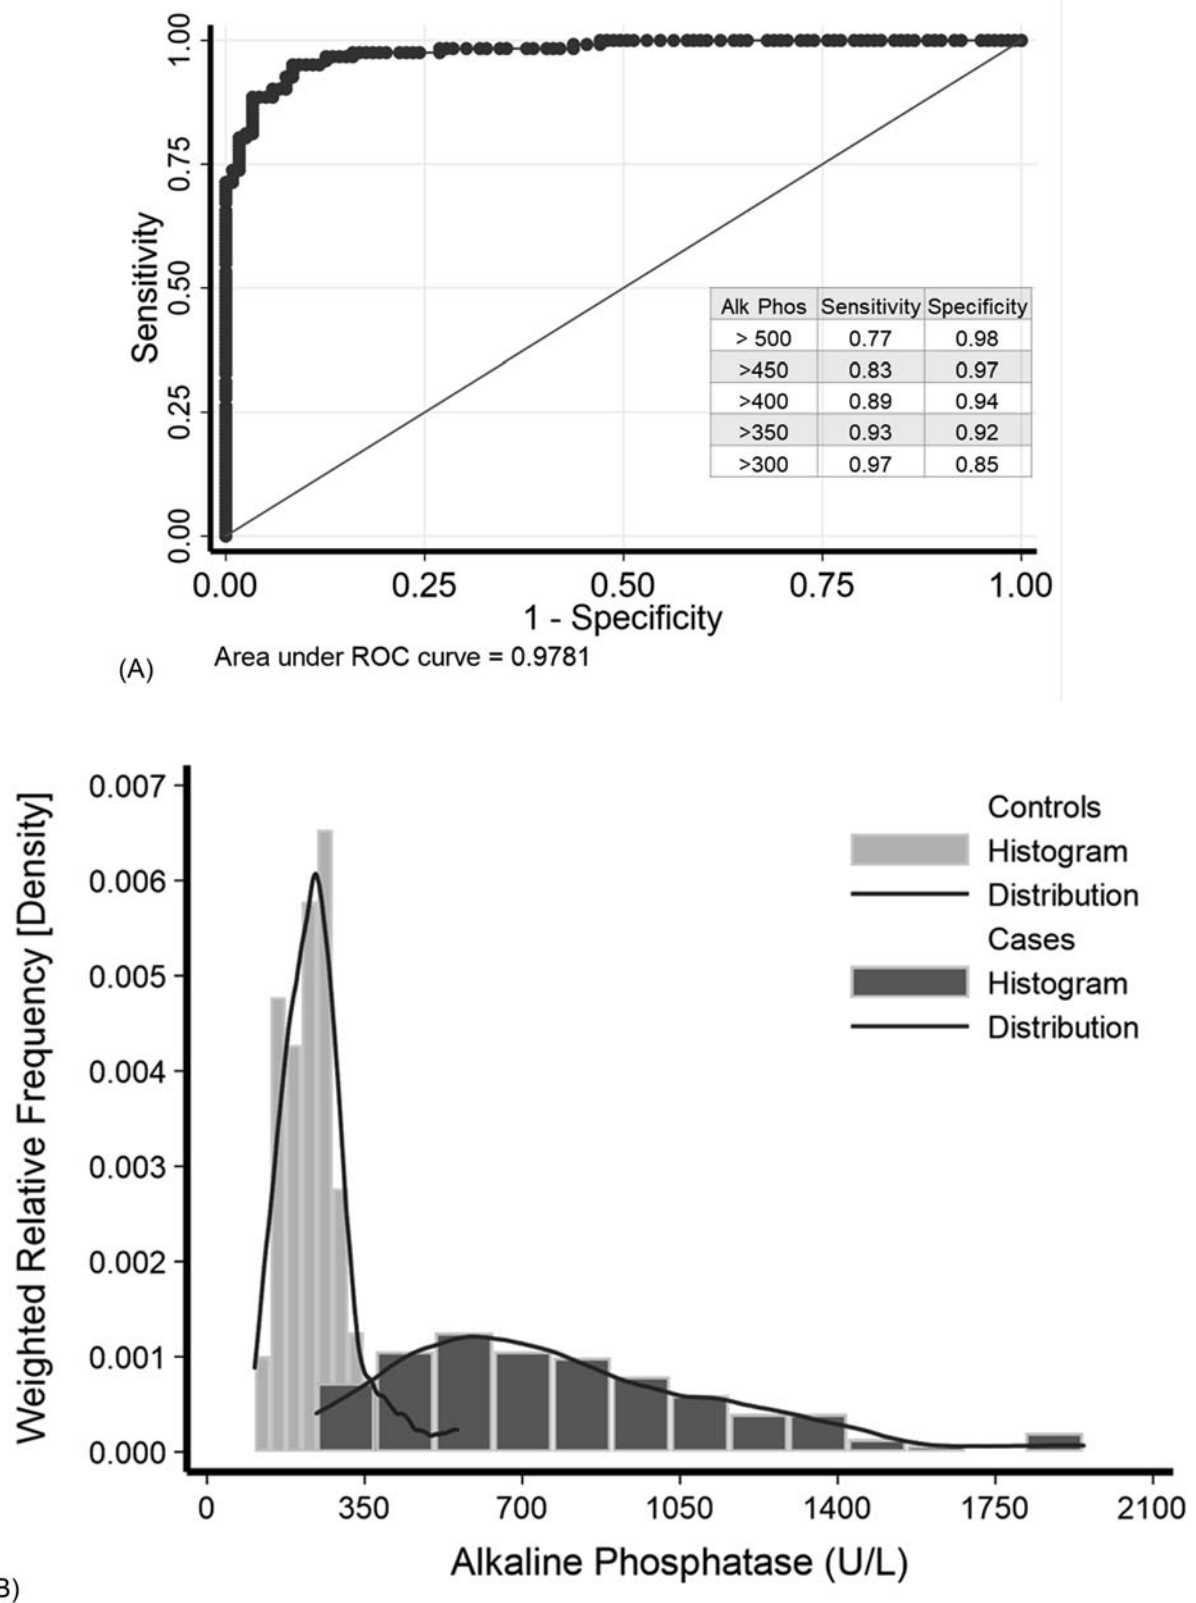

With widespread vitamin D deficiency in many countries, vitamin D supplementation is unlikely to be an effective means of combating the disease on a community basis, and food fortification should be considered a complementary solution [321].

Nutritional rickets and its consequences are preventable global public health problems [322]. The clinical manifestations are the “the tip of the iceberg,” indicating widespread vitamin D and/or calcium deficiencies [138]. Prevention programs can be targeted to reach high-risk groups of the population, or they can use an universal approach to cover all members of the population. Combining both approaches is most effective. Public health interventions first require assessment of the disease burden and the magnitude of the problem, as prevention programs have their greatest impact in populations with a high prevalence of nutritional rickets. The burden of nutritional rickets is measured both by its prevalence and by its health consequences. The prevalence of nutritional rickets is greatest in Asia, the Middle East, and Africa. In high-income countries, the disease burden is greatest in ethnic minority, immigrant, and refugee populations. Case ascertainment of nutritional rickets requires a uniform case definition, based on clinical features, followed by confirmatory radiographs, which are the gold standard for diagnosis of active rickets. Consensus is needed to determine the best methods to estimate the prevalence of rickets, particularly in communities with limited resources [323]. Clinical signs of rickets have been used extensively, but are likely to overestimate the prevalence and depend on clinical skills. Population screening for rickets utilizing the measurement of serum 25(OH)D or radiographs is not recommended [22,324]. Alkaline

phosphatase measurements have also been considered as a biomarker of active rickets, but the specificity of elevated levels indicative of rickets depends on the underlying prevalence of active rickets in the community. Recently a study from Nigeria has highlighted the good discriminatory value of an elevated alkaline phosphatase value to differentiate those children with active rickets from community controls [216] (Fig. 63.4). Because the incidence of nutritional rickets is an indicator of vitamin D and calcium deficiency within the population, rickets surveillance in low- and middle-income countries would highlight areas in greatest need of a vitamin D status survey or intervention [325].

Nutrient supplementation is the fastest way to improve the micronutrient status of individuals or targeted populations [324]. Programs that universally supplement infants with vitamin D 400 IU/day from birth to 12 months of age have prevented nutritional rickets in healthy infants who have an adequate calcium intake [126,299,300]. Successful vitamin D supplementation in Turkey resulted from training parents how to give vitamin D, explaining the benefits, and continuous monitoring and evaluation [87,300]. As a result of this program, the prevalence of rickets declined from 6% to 0.1%, demonstrating the success of an infant vitamin D supplementation program. Beyond 12 months, children at risk should continue vitamin D supplements. Vitamin D supplementation is best integrated into existing childhood primary health and antenatal care programs, which already provide recommended micronutrients and immunizations. Daily vitamin D supplementation of infants effectively improves their vitamin D status [326,327], but adherence is the primary obstacle with this approach. Single large doses of oral vitamin D, given to infants as part of an immunization program, provide a good opportunity to ensure that children receive adequate vitamin D (for example, 50,000 IU every 2 months [325,328]). This approach is similar to the administration of high-dose vitamin A supplementation in low-income countries to reduce morbidity from measles. The effects of a single dose of vitamin D can last for 3 months or more, and this approach may be preferred when adherence to daily supplementation is problematic.

Food fortification is a universal strategy that reaches an entire population. Food fortification has a less immediate, but ultimately a wider and more sustained impact than supplementation programs, and fortification is generally more cost-effective than other interventions [325]. Vitamin D is naturally found in only a limited number of foods, and apart from food fortification, dietary intakes have little impact on vitamin D status. Fortifying commonly consumed staple foods with vitamin D and calcium based on dietary patterns safely provides adequate intake to prevent deficiency at minimal cost.

**FIGURE 63.4** The utility of serum alkaline phosphatase in diagnosing active rickets in children with suspected dietary calcium deficiency using a case-control study. The controls were age- and sex-matched with the cases of active rickets, which were diagnosed using radiographs of the knees and wrists. (A) is a plot of the receiver operating characteristic curve plotting true positive rate (sensitivity) against false positive rate (1-specificity). (B) depicts the alkaline phosphatase values in cases and controls. *Reproduced with permission from Ref. [216].*

Food fortification effectively prevents nutritional rickets and improves the vitamin D status of children [329,330]. Following vitamin D fortification of milk in North America and of milk, margarine, and cereals in the United Kingdom, the prevalence of rickets dramatically declined, so much so that it was considered almost eradicated [331].

Although the untargeted fortification of foods other than milk and infant milk formulas has been used in the past, the problems of hypercalcemia experienced in the United Kingdom after World War II led to it falling into disfavor (as discussed earlier in this chapter). However, many of these cases of infantile hypercalcemia were likely to be due to impaired metabolism of vitamin D (inactivating mutations of the *CYP24A1* gene encoding the 24-hydroxylase enzyme) rather than to excessive vitamin D alone [332]. Women with an inactivating *CYP24A1* mutation are also at risk for hypercalcemia in pregnancy [333,334]. Targeted food fortification has been studied in the Asian community in Great Britain as a means of reducing the high prevalence of vitamin D deficiency in both adults and children in that community [335]. Fortification of chapatti flour at a level of 6000 IU/kg for 6 months produced a sustained and significant rise in serum 25(OH)D concentrations comparable with those achieved by a weekly dose of 3000 IU vitamin D. Serum calcium and phosphorus values rose, and the number of subjects with biochemical abnormalities suggestive of rickets fell. The authors concluded that fortification of chapatti flour is a cheap and effective method of preventing vitamin D deficiency in the Asian community in Britain and has the advantage over daily or intermittent vitamin D supplementation as adherence to supplementation is often poor. Fortification of widely consumed food vehicles is most effective when the program is mandatory and enforced [325]. Nevertheless, food fortification can be a controversial public issue. In the United States not only have there been isolated reports of vitamin D toxicity related to inadequate monitoring of the fortification process [14], but underfortification can also be a problem [336].

Low dairy product intake, a common situation in low-income countries, is a risk factor for nutritional rickets from inadequate dietary calcium in children over the age of 12 months. In areas with inadequate calcium intakes, indigenous food sources of calcium or food fortification with low-cost calcium carbonate can be promoted or subsidized [104,337]. Successful food fortification requires selection of culturally appropriate and affordable staple foods [338,339]. Government regulation is necessary to establish food fortification requirements and monitor the fortification process.

Because correction of vitamin D deficiency is relatively easy, inexpensive, and cost efficient through fortification, there have been multiple calls to eradicate

rickets globally through fortification programs [22,325,340]. Fortification of habitually consumed foods is the most effective means of assuring adequate vitamin D status and prevention of rickets at a population level. Food fortification and supplementation programs are synergistic interventions [341]. A review of food-based solutions for preventing vitamin D deficiency, such as fortification and supplementation, found that 25(OH)D values > 50 ng/mL (125 nmol/L) were rare, and no adverse events were observed [342]. There are limited data regarding vitamin D intake and exposure in LMICs, and improving these estimates will aid in identifying countries where a 25(OH)D assessment survey is necessary [325].

The effectiveness of public health interventions can be assessed by determining adherence to recommended vitamin D and calcium intakes and by case surveillance for nutritional rickets. Periodic nutrition surveys of dietary intakes and vitamin D status enable policy-makers to assess the level of population risk for nutritional rickets. A Cochrane Review concluded that the effects of preventive measures for nutritional rickets should be investigated in different countries, different age groups, and in children of different ethnic origins [343]. Assessing the micronutrient status of populations; monitoring and evaluating the impact of strategies for the prevention and control of micronutrient malnutrition; and tracking related trends over time are included in the mandate of the WHO [344].

## 11. Dietary calcium deficiency

Conventional wisdom would have it that nutritional rickets is primarily due to vitamin D deficiency, although dietary calcium intake modulates the severity and rapidity of onset of the disease [345,346]. However, accumulating evidence implicates low dietary calcium intakes as a cause of rickets in the face of serum 25(OH)D concentrations above values generally associated with vitamin D-deficient rickets (<25 nmol/L).

Isolated case reports of rickets developing in infants and toddlers, who were placed on very low calcium diets, have been published [347–350]. Their clinical and biochemical presentations were very similar to those of infants with vitamin D deficiency; however, in three of the five infants, serum 25(OH)D and 1,25(OH)<sub>2</sub>D values were reported to be greater than 9 ng/mL (22.5 nmol/L) and 118 pg/mL (295 pmol/L), respectively. In none of the five infants was a therapeutic trial of calcium supplementation of the diet alone tried; however, the clinical and biochemical presentation suggested to the authors that dietary calcium deficiency was the primary factor responsible for the development of rickets.

More convincing evidence of dietary calcium deficiency as a cause for rickets in children comes from studies in South Africa [351,352], Nigeria [353–356], India [105,317], and Bangladesh [106,357], where the staple diets of children are characteristically low in calcium because of the lack of readily available dairy products and the low calcium content of the cereals (maize [corn], cassava, yam, rice, and plantain) [92,138,358,359]. In the South African children, dietary calcium intakes have been estimated to be between 90 and 300 mg/day in those children suffering from rickets compared with between 200 and 500 mg/day in age-matched controls [358], while in the Nigerian children, both patients and controls had similar but very low calcium intakes (200 mg/day) [167]. In children with active rickets in Bangladesh, mean calcium intakes were 156 mg/day compared with 323 mg/day in controls [357].

In South Africa, the children typically came from rural areas and presented with signs and symptoms of rickets between the ages of 4 and 15 years (Fig. 63.4) [360], while in Nigeria, they presented younger, at a mean age of approximately 4 years [354]. In the South African series, half the children presented with knock-knees, while the others presented with either bow-legs or wind-swept deformities (Fig. 63.5). Bow-legs were more common in the Nigerian children, probably reflecting their earlier age of presentation [167]. Unlike vitamin D deficiency, symptoms of muscle weakness were characteristically absent in older children with dietary calcium deficiency.

Radiologically, the features are typical of calciopenic rickets with osteopenia and features of hyperparathyroidism being frequent findings. The severity of the metaphyseal changes is variable (Fig. 63.6). Older children (teenagers) may have no radiologic changes of rickets despite features of osteomalacia on the iliac crest bone biopsy [361]. Younger children may show evidence of only minor degrees of impaired endochondral calcification, while in others the metaphyseal changes may be quite marked. In a Nigerian study, the degree of severity of radiologic rickets was correlated with serum alkaline phosphatase values [214].

The biochemical features are similar to those of other causes of calciopenic rickets. Hypocalcemia, low urinary calcium excretion, and elevated serum PTH and alkaline phosphatase concentrations are characteristics, while serum phosphorus values are variable and may be within the reference range for age [92,138,357,359]. Serum 25(OH)D values tend to be lower in those with active rickets than controls, but are often above values generally considered to be associated with vitamin D deficiency (mean 16.4 ng/mL (41 nmol/L), 14.4 ng/mL (36.0 nmol/L), and 9.5 ng/mL (23.7 nmol/L) in the South African, Nigerian, and Bangladeshi children,

respectively), and 1,25(OH)<sub>2</sub>D concentrations are markedly elevated [354,355,362]. In a Nigerian study [92] and in the South African children [221], serum osteocalcin levels were similar to those of nonrachitic controls in the majority of patients, although another report from Nigeria found slightly higher levels in rachitic patients than controls [210].

In a small number of children who had iliac crest bone biopsies, they revealed evidence of osteomalacia and hyperparathyroidism in those children who have radiologic features of rickets [352], while in the teenagers without radiologic changes but lower limb deformities, the histologic picture varied from that of decreased bone volume, through features of hyperparathyroidism, to frank osteomalacia associated with hyperparathyroidism [361].

In both the Nigerian and South African studies, clinical, biochemical, and radiologic healing has been achieved through increasing the calcium intake of the children to between 800 and 1500 mg/day without the administration of vitamin D supplements [92,351]. A study using a calcium supplement of only 350 mg/day reported complete healing within 6 months [356]. A study in Nigeria showed that a daily elemental calcium dose of 1000 mg was associated with more rapid healing than 500 mg/day, but the use of 2000 mg/day did not have greater benefit than 1000 mg [363]. In a randomized controlled trial, calcium supplements alone or with vitamin D were equally effective in healing the bone disease and were significantly better than vitamin D therapy alone [354]. However, other studies suggest that combining vitamin D with calcium may result in improved healing of rickets, even when caused by dietary calcium deficiency [271,364]. In the majority of the South African children, orthopedic corrective surgery has been necessary to correct the deformities of the legs once biochemical and radiologic healing has occurred. This has not been the pattern in the younger Nigerian children with rickets, who have shown remarkable modeling and straightening of deformities without orthopedic surgical intervention [356] (Fig. 63.7). Similarly, studies from Bangladesh suggest that early medical treatment reduces the number of children requiring corrective surgery [106].

The data available from epidemiologic studies conducted in a rural area in South Africa in which a number of the affected children live, suggested that asymptomatic dietary calcium deficiency was prevalent in schoolchildren living in the area. Some 13% of children between the ages of 7 and 12 years were hypocalcemic, 41.5% had elevated alkaline phosphatase concentrations, and 76% had low urinary calcium excretion [365]. It is unclear if these children have long-term sequelae because of the poor calcium intakes. However, studies do indicate that asymptomatic children with

**FIGURE 63.5** The clinical presentation of children with dietary calcium deficiency. The deformities are typically more severe in the legs with a predominance of knock-knees or windswept deformities. Upper limb deformities are usually mild if present at all. *Reproduced with permission from Ref. [360].*

biochemical abnormalities living in the rural community have lower appendicular bone mass than those with normal biochemistry [358] and that children in the community as a whole have lower appendicular bone mass than their urban peers [366].

Although dietary calcium intakes in children with biochemical changes suggestive of dietary calcium deficiency are very low, it is unclear what role the high

phytate or oxalate contents of the diet play in aggravating the symptoms. Nevertheless, biochemical improvement can be achieved by supplementing the children with 500 mg calcium daily [367]. The finding of similarly low dietary calcium intakes in patients with rickets and age-matched controls in Nigeria is intriguing [167], as it suggests that factors other than low dietary calcium intakes might influence the

**FIGURE 63.6** The radiographic features of dietary calcium deficiency rickets in the lower limbs of a child. The long bones are osteopenic with deformities characteristic of long-standing rickets. The metaphyses show evidence of impaired mineralization and growth arrest lines, and the physes of the femurs and tibias are widened and irregular.

development of rickets in affected children. Such factors might include differing amounts of inhibitors of calcium absorption in the diet, differing vitamin D status [137], differing growth rates and therefore calcium requirements in the children, or genetic differences that make the rachitic children less able to adapt to low dietary calcium intakes than control subjects. A number of these factors are currently under investigation. A small study has found that there are significant differences in the frequency of vitamin D receptor polymorphisms between affected and control children with the *FF* genotype being

more common in children with rickets, but the significance of these findings is unclear at present [47]. One of the hallmarks of dietary calcium deficiency, which differentiates it from vitamin D deficiency, is the markedly elevated serum concentrations of  $1,25(\text{OH})_2\text{D}$  in untreated subjects. These values are even higher than those found in age-matched controls, who had dietary calcium intakes similar to those who developed rickets [167]. In a situation of low dietary calcium intake, it would be expected that these high  $1,25(\text{OH})_2\text{D}$  concentrations would maximize intestinal calcium absorption. Studies using

stable isotopes of calcium have confirmed this hypothesis in children with active rickets in Nigeria [231,368]. The mean intestinal fractional calcium absorption of just over 60% in these children is much greater than that reported in subjects with vitamin D deficiency (10%–15%) [369] and is in keeping with the primary pathogenetic mechanism being dietary calcium lack rather than vitamin D deficiency.

1,25(OH)<sub>2</sub>D is the primary factor regulating intestinal calcium absorption and thus is responsible for the acquisition and preservation of mineralized bone mass [370]. 1,25(OH)<sub>2</sub>D shifts calcium from bone to serum during a negative calcium balance. Hogler has emphasized that low vitamin D or low calcium intake alone does not cause problems; however, rickets can develop if both are insufficient or deficient as shown in Fig. 63.1 [371]. A recent reanalysis of the data obtained from studies in Nigeria has highlighted the interaction between 25(OH)D levels and dietary calcium intake in the pathogenesis of rickets in children on low dietary calcium intakes [137] (Fig. 63.8). Calcium-deficient rickets causes secondary hyperparathyroidism and increased 1,25(OH)<sub>2</sub>D production which in The Gambia was associated with an increase in serum FGF23 [370]. 1,25(OH)<sub>2</sub>D production also stimulates the production of inhibitors of mineralization such as pyrophosphate

and osteopontin. Therefore, not only vitamin D deficiency but also an increase in 1,25(OH)<sub>2</sub>D from calcium deficiency impairs mineral deposition resulting in rickets [372]. It is possible that relative vitamin D insufficiency might play a role in children with presumed dietary calcium deficiency rickets, as 25(OH)D concentrations are lower in children with active rickets than in their age-matched controls [137,167]; however, the addition of vitamin D to the calcium supplements in a randomized controlled trial did not significantly improve the response of rachitic children to treatment [354]. Nevertheless, bolus administration of vitamin D (50,000 IU) to untreated rachitic children resulted in a rapid and marked rise in 1,25(OH)<sub>2</sub>D concentrations, which peaked on day 3 and then declined over the following 10 days [373]. These findings suggest that there might be relative substrate (25(OH)D) deficiency, which is corrected by the provision of the bolus of vitamin D. A more recent randomized controlled trial in Nigerian children with nutritional rickets from insufficient dietary calcium showed that children benefitted from both calcium, in the form of limestone, and vitamin D supplementation to promote more rapid healing of the rickets [271]. These and other study findings suggest that the prevention of nutritional rickets in high-risk populations should include fortification of staple foods

**FIGURE 63.7** The response to nonsurgical treatment of lower limb deformities in children with rickets due to dietary calcium deficiency. Treatment consisted of a combination of calcium and vitamin D supplements. (A) Child at the age of 2.7 years prior to commencement of treatment. (B) The same child following healing of the rickets. (C) Another child aged 4.5 years prior to treatment. (D) The same child following biochemical and radiological healing of the rickets.

with a combination of calcium (possibly in the form of limestone) and vitamin D since an increased intake of calcium protects individuals from the effects of vitamin D deficiency [137,374] and vitamin D supplementation may promote more rapid healing in calcium-deficient rickets [271].

## 12. Rickets of prematurity or metabolic bone disease of prematurity

Rickets or osteopenia of prematurity, also referred to as metabolic bone disease of prematurity (MBDP), is a reduction in bone mineral content presenting with a combination of biochemical abnormalities and/or radiological features of rickets in premature infants. Although not usually discussed in sections on nutritional rickets, there is no doubt that a major contributing factor for developing the disease is a relative deficiency of phosphate intake in very-low-birth-weight infants during the first 3 months of life. The incidence of MBDP is reported to be between 23% and 32% in very-low-birth-weight (<1500 g) and up to 50% in extremely low-birth-weight infants (<1000 g) [375,376]. The main risk factors for reduced bone mineralization are low gestational age and birth weight [375–378].

Approximately 80% of fetal bone mineral accretion occurs in the third trimester of pregnancy with 300 mg/day of calcium being transferred to the fetus between 35 and 38 weeks' gestation [379]. Calcium, phosphate, and magnesium are actively transported across the placenta from the maternal circulation even if maternal supplies are low. The high fetal–maternal gradient of minerals allows the fetus to have “hypercalcemia” (compared to maternal concentrations) to promote skeletal formation with low levels of parathyroid hormone (PTH), calcitriol, and sex steroids [380]. The calcium-sensing receptor maintains suppression of PTH for fetal hypercalcemia to be maintained [379]. High calcitonin levels found in the fetus also promote mineral deposition. Parathyroid hormone–related peptide (PTHrP) has an additive role in the regulation of mineral homeostasis and also stimulates bone formation [379]. Premature infants lack exposure to the third trimester intrauterine fetal environment during which period a greater growth and intake of minerals occur. The consequences of preterm birth increase the nutritional and metabolic stresses these neonates have to adapt to. Besides the reduced placental transfer of calcium and phosphate in preterm infants, these additional risk factors, often in combination, predispose these infants to develop MBDP. The ante- and postnatal risk factors for MBDP are listed in Table 63.2 [380].

**TABLE 63.2** Antenatal and postnatal risk factors of metabolic bone disease of prematurity.

Antenatal	Postnatal
Placental insufficiency	Prolonged total parenteral nutrition > 4 weeks
Preeclampsia	Bronchopulmonary dysplasia
Chorioamnionitis	Necrotizing enterocolitis
Males	Liver disease or severe cholestasis
Genetic polymorphisms (vitamin D receptor, estrogen, collagen alpha I)	Renal disease
Neuromuscular disorders	Medications (loop diuretics, methylxanthines, glucocorticoids)
Intraventricular hemorrhage Periventricular leukomalacia	Prolonged mechanical ventilation and immobilization

*Adapted with permission from Ref. [380].*

In addition to the contributory ante- and postnatal factors, the preterm infant is most likely to develop MBDP from suboptimal nutritional support in the postnatal period. Breast milk feeds are the ideal choice of nutrition but the gradual initiation of these feeds and the preterm infants' intestinal immaturity are rate limiting factors to the optimal absorption of calcium and phosphate. Due to the decreased intake and/or absorption of calcium and phosphate, the preterm infant needs special fortified formulas or breast milk in view of the low levels of phosphorus and calcium in breast milk [381,382]. The average absorption of dietary calcium is 60% in breastfed infants, and the amount can be increased by human milk fortifiers containing highly soluble calcium glycerophosphate [383,384]. Preterm infant's phosphorus intake is as low as 0.5 mmol/kg/day postnatally compared with 2.1–2.6 mmol/kg/day in utero [381]. It is important to consider that prolonged total parenteral nutrition (TPN) and early aggressive parental nutrition providing approximately 4 g/kg/day of intravenous protein in the first week of life has been associated with severe hypophosphatemia in neonates with birth weights <1250 g [385]. Calcium and phosphorus intake levels of 3.4 mmol/kg/day and 2.6 mmol/kg/day, respectively, with adequate protein intake are required to achieve a postnatal average weight gain of 17 g/kg/day (the fetal growth rate before 35 weeks of gestation). Any protein supplied above 2 g/kg/day will require an additional phosphorus intake to ensure adequately accretion. Protein intake of 3.5 g/kg/day promotes good extrauterine growth [385,386], but hypophosphatemia develops due to the infants' high metabolism and utilization of phosphorus [385].

Clinical features of MBDP such as splayed sutures, craniotabes, frontal bossing, widened wrists and

enlarged costochondral junctions or rachitic rosary with tachypnea, fractures, and postnatal growth failure can manifest between 3 and 12 weeks of age [387].

The routine baseline serum biochemical markers for screening should include calcium, phosphate ( $\text{PO}_4$ ), alkaline phosphatase (ALP), PTH, and a calculation of the renal tubular reabsorption of phosphate (TRP). The American Academy of Pediatrics Committee on Nutrition (AAP-CON) recommends screening all very-low-birth-weight infants for MBDP with serum  $\text{PO}_4$  and ALP starting at 4–5 weeks of age [388]. Thereafter, the assessment should include weekly or biweekly serum  $\text{PO}_4$  and ALP [389,390]. According to AAP-CON, an ALP level  $>500$  IU (depending on the assay methodology used) and  $\text{PO}_4$  levels  $<3.5$ – $4$  mg/dL ( $1.13$ – $1.29$  mmol/L) are suggestive of MBDP [388]. Kavurt et al. [391] studied VLBW infants who received total parental nutrition (TPN) from the first day of life; of the 254 infants, metabolic bone disease was diagnosed in 37%, 72 (28%) developing radiological evidence of rickets and 24 (0.9%) only biochemical abnormalities. In those with radiological evidence of rickets, the serum ALP was significantly higher and the serum  $\text{PO}_4$  level significantly lower than in those with no radiological changes. The serum calcium levels were similar and normal in both these groups [391]. However, no single value of ALP or  $\text{PO}_4$  was related to radiological findings of MBDP [392]. An X-ray of the wrist and/or knee is recommended in VLBW infants when two values of ALP measured at least 1 week apart exceed 800 IU/L [387]. Backström et al. reported that ALP levels  $>900$  IU/L and persistently low  $\text{PO}_4$  levels  $<5.6$  mg/dL ( $1.81$  mmol/L) in VLBW preterm infants  $<33$  weeks' gestation have a diagnostic sensitivity and specificity of 100% and 70%, respectively, to diagnose MBDP [393]. Hypophosphatemia is the primary biochemical alteration in MBDP causing a reduction in PTH and FGF23 secretion with an increase in TRP. The decrease in phosphate stimulates 1,25 dihydroxyvitamin D synthesis and increases intestinal calcium absorption causing hypercalcemia, hypercalciuria, and

nephrocalcinosis. Neonatal TRP is generally 78%–91%, and a value of  $>95\%$  is a significant marker of insufficient  $\text{PO}_4$  supplementation [389,394]. The TRP is calculated using the following formula:  $[1 - (\text{urinary phosphate/urinary creatinine} \times \text{serum creatinine/serum phosphorus})] \times 100$ . Elevated PTH levels  $>100$  pg/mL suggest secondary hyperparathyroidism and, in relation to the TRP, can discriminate between the underlying causes of hypophosphatemia. A high TRP with a low or normal PTH suggests phosphate deficiency, while a low TRP and high PTH suggests vitamin D or calcium deficiency [394].

MBDP tends to spontaneously resolve over time; however, it is necessary to supplement mineral postnatally to prevent the development of severe complications related to the bone disease and hypophosphatemia. It is considered appropriate to adopt preventative strategies of optimizing total parental nutrition and early achievement of full enteral feeding [380]. The essential preventative measures are to avoid postnatal risk factors, improve nutrition, and limit the use of chronic drugs that reduce mineral stores and enhance bone resorption. Adequate amounts of calcium and phosphate intake with TPN must be ensured and augmented during transition to enteral feeding and prolonged use of oral supplementation is further recommended during full enteral nutrition. The current practice recommendations when providing TPN in the first weeks of life are 40–120 mg/kg/day ( $1$ – $3$  mmol/L/kg/day) for calcium and 30–70 mg/kg/day ( $0.9$ – $2.2$  mmol/kg/day) for phosphate as shown in Table 63.3 [380,395]. At TPN fluid intakes of 150 mL/kg/day, 75–90 mg/kg/day ( $1.8$ – $2.2$  mmol/L/kg/day) for calcium and 60–70 mg/kg/day ( $1.9$ – $2.2$  mmol/kg/day) for phosphate are recommended with a ratio ranging from 1.5 to 1.7:1, to ensure a higher mineral accretion [395,396]. The recommended daily oral intake of calcium and phosphate also varies depending on the different consensus guidelines from the United States and European states outlined in the table [380,397,398]. The higher intake of protein

**TABLE 63.3** Treatment and supplementation of calcium, phosphate, and vitamin D in preterm infants receiving TPN and transitioned to enteral feeds,  $<1500$  g.

	TPN 1st few weeks	TPN after 1st few weeks (fluid intake 140–150 mL/kg/day)	Full enteral feeding
Calcium	40–120 mg/kg/day ( $1.0$ – $3.0$ mmol/kg/day)	75–90 mg/kg/day ( $1.8$ – $2.2$ mmol/kg/day)	140–160 mg/100 kcal (AAP) 70–140 mg/100 kcal (ESPGHAN)
Phosphate	31–71 mg/kg/day ( $1.0$ – $2.2$ mmol/kg/day)	60–70 mg/kg/day ( $1.9$ – $2.2$ mmol/kg/day)	95–108 mg/100 kcal (AAP) 50–86 mg/100 kcal (ESPGHAN)
Vitamin D	160–280 IU/day	160–280 IU/day	200–400 IU/day (AAP)

and calories in TPN within the first few days of life helps increase the cellular uptake of phosphate.

Fortified human milk and preterm formulas meet the needs of the growing preterm infant as opposed to unfortified human breast milk, and these fortified milks are recommended until 36 weeks' gestation or at least until the infant reaches 2000 g. Phosphate supplementation should be commenced when serum phosphate level is  $<5.5$  mg/dL (1.3 mmol/L) to promote bone mineralization and prevent hypercalciuria [388]. Serum calcium levels are usually normal or marginally high due to elevated 1,25 dihydroxyvitamin D in response to hypophosphatemia. A calcium: phosphate ratio of 2:1 should be maintained to avoid hypercalciuria, nephrocalcinosis, and extraskeletal calcifications [394]. Calcium supplementation should be given if the TRP is reduced and PTH is elevated. The dose of vitamin D supplementation remains controversial in preterm infants as the different nutrition and pediatric societies recommend differing doses. It has been shown that 200–400 IU/day of vitamin D is sufficient to prevent osteopenia of prematurity and the AAP recommends 200–400 IU/day [388,399], although 1000 IU/day has sometimes been recommended in the literature. If the 25(OH)D levels are  $<30$  nmol/L, then higher doses of vitamin D may be warranted [397]. In the presence of concurrent liver or renal disease, 1,25 dihydroxyvitamin D (calcitriol) can be added to treat hypocalcemia [397]. If the infants sustain fractures that are often incidentally found, these fractures usually heal without orthopedic intervention unless they are severe and require skilled management (splinting, traction, or fixation) to promote better healing.

The chronic use of diuretics and steroids for bronchopulmonary dysplasia and caffeine that is commonly administered to treat apnea of prematurity are significant predisposing risk factors for MBDP. Both caffeine and furosemide have a diuretic effect and increase renal excretion of calcium. Caffeine increases osteoclastogenesis and causes hypercalcemia, thus reducing bone mineral content [400,401]. The exact mechanism of the action of steroids on bone in premature infants has not been studied but is likely to be due to both the direct and indirect effects of steroids on bone. The direct effects can occur rapidly with loss of bone mineral density due to increased bone resorption by increased expression of cytokines promoting osteoclastogenesis and thereafter chronically with a slower phase associated with decreased bone formation through the inhibition of osteoblast differentiation and the promotion of apoptosis [402,403]. Ali et al. studied 109 premature Canadian infants born  $<31$  weeks' gestation and  $<1500$  g who were admitted for 12 weeks in an intensive care unit and had radiological evidence of osteopenia of prematurity [378].

These infants had been receiving caffeine, steroids, diuretics, and vitamin D. There was a positive association of steroid cumulative dosages and the duration of caffeine use with osteopenia of prematurity in this study [378]. The chronic use of medication affecting bone mineral metabolism should be limited.

MBDP is generally a self-limiting condition in premature infants unless accompanied by severe osteopenia, underlying fractures and symptomatic biochemical abnormalities. Fig. 63.9 details an algorithmic approach to managing MBDP [397]. When a healthy preterm infant receives full enteral feeding with either fortified human milk or preterm formula within 2–3 weeks after birth, the infant should not be subjected to unnecessary investigations for MBDP.

### 13. The pathogenetic spectrum of nutritional rickets

Nutritional rickets has traditionally been viewed as being due to vitamin D deficiency through either an inadequate dietary intake or insufficient skin exposure to ultraviolet radiation, although more recently the role of a low dietary calcium intake in the face of a relatively normal vitamin D status has been considered to be an important pathogenetic mechanism in some LMICs. In addition to the classical causes of nutritional rickets, dietary intakes of calcium and phosphate are considered to play important roles in the pathogenesis of the metabolic bone disease of prematurity [397]. However, these pathogenetic concepts are too simplistic. Early studies by Mellanby [404] had shown the effect of cereals in exacerbating the clinical development of vitamin D deficiency rickets in dogs. Studies in baboons have confirmed these findings [348].

The resurgence of rickets and osteomalacia in the Asian community in Great Britain provided the impetus for detailed studies into the pathogenesis of vitamin D deficiency and bone disease in that community. Although vitamin D deficiency as assessed by circulating 25(OH)D concentrations is the hallmark of the disease in Asians [194,405,406], the mechanisms for the low vitamin D status and the high prevalence of rickets were unclear. It is apparent that the majority of Asians in Britain do not spend less time outdoors than their Caucasian counterparts [407]. Further, although they have darker skins than Caucasians, which might reduce the amount of vitamin D formed in response to sunlight exposure, Afro-Caribbean immigrants living in Britain have even darker skins, yet fewer cases of rickets have been described in this ethnic group [136]. Within the Asian community, studies have highlighted that risk factors for the disease include living at high latitude, Hindu

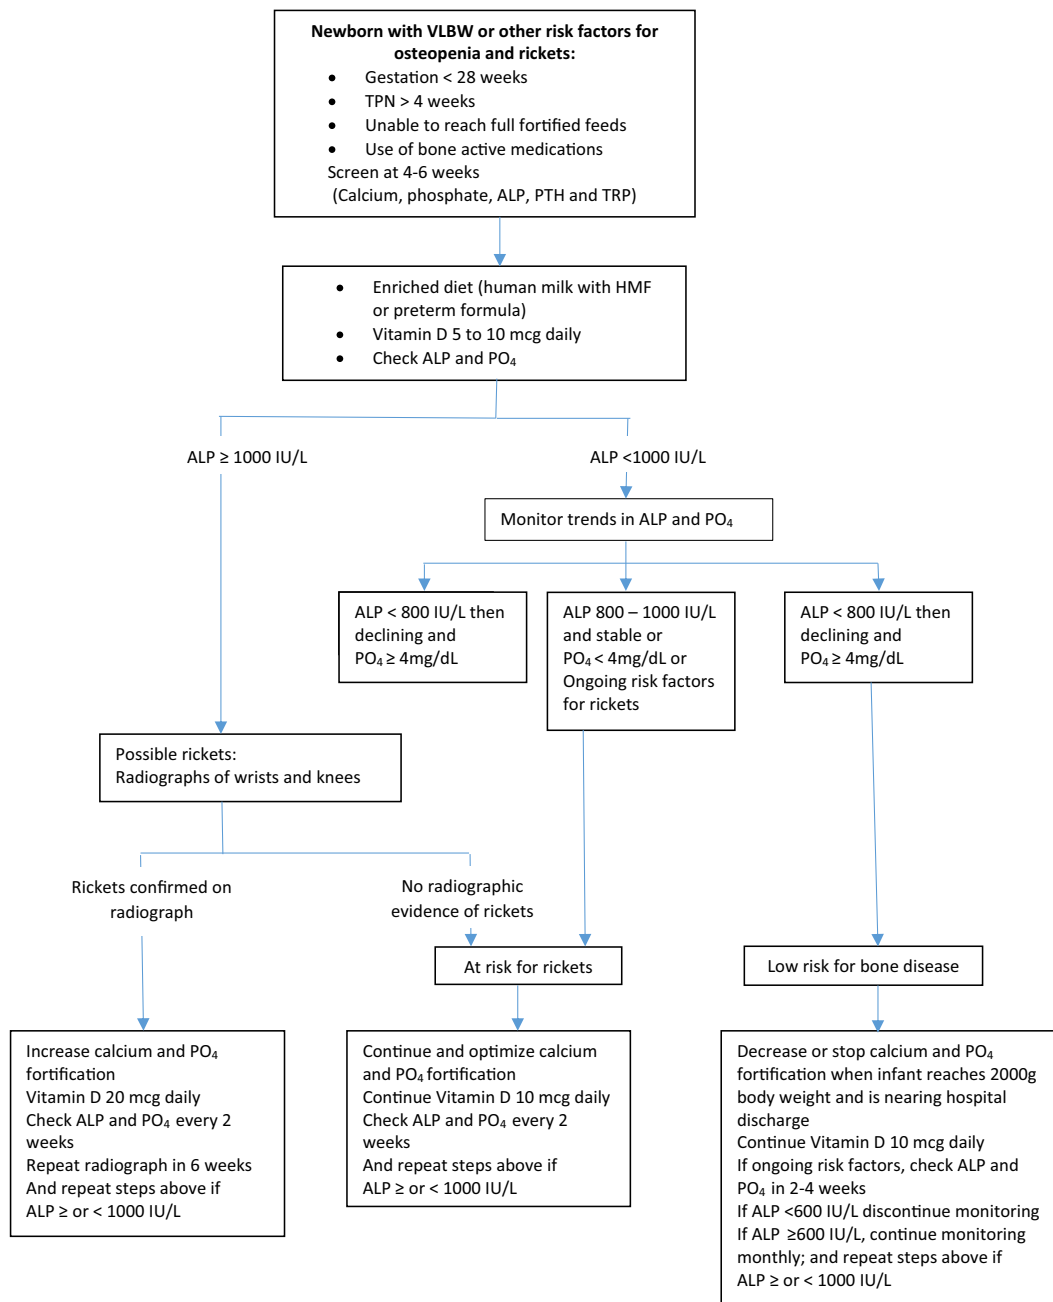

**FIGURE 63.8** The effect of changing 25-hydroxyvitamin D concentrations and dietary calcium intakes of the risk of developing rickets in Nigerian children. *Reproduced with permission from Ref. [137].*

religion, immigration from East Africa, vegetarianism, high-fiber diets, and the consumption of chapatti [134,135,408]. The association with vegetarianism, high-fiber diets, and cereals of high extraction suggests that dietary factors play a role. Support for this comes from two studies that have documented healing of rickets on removing chapattis from the diet [409,410], although this is not a universal finding [133].

Over the past four decades, research has shown that both high-fiber diets and intestinal malabsorption reduce the serum half-life of 25(OH)D by approximately one-third [411,412]. Further, experiments in rats have demonstrated that an elevation in serum 1,25(OH)<sub>2</sub>D concentrations, either by exogenous administration or endogenously through a low calcium diet, increases the metabolic clearance rate of 25(OH)D without altering its rate of production [232,413,414]. In these studies, the fall in serum 25(OH)D levels could be accounted for by an increase in polar metabolites appearing in the feces. Similar findings have been reported from studies in humans [233,415]. Conversely, increasing the calcium content of the diet has been shown to increase serum 25(OH)D and decrease serum 1,25(OH)<sub>2</sub>D concentrations [416]. Thus, these studies

convincingly show that dietary calcium and phytate content influences the catabolism of 25(OH)D through altering serum 1,25(OH)<sub>2</sub>D concentrations. In the face of a marginal vitamin D status due to limited skin synthesis of vitamin D and the low dietary vitamin D content of the diet, the increased catabolism is sufficient to precipitate vitamin D deficiency and clinical rickets and osteomalacia.

Thus, nutritional rickets has a spectrum of pathogenic mechanisms ranging from pure vitamin D deficiency associated with adequate calcium intakes, as might occur in the breastfed infant, at one end of the spectrum, to pure dietary calcium deficiency with an adequate vitamin D status, as documented in some Nigerian and South African rural children, at the other end [137,417] (Fig. 63.10). In between these two extremes lies the situation exemplified by the Asian community in Britain, where both poor calcium intakes or absorption and marginal vitamin D status combine to lead to frank rickets. It is likely that the high prevalence of rickets in vegetarian or immigrant children reported from the United States [56,57], Norway [418], Holland [419,420], and a number of tropical and subtropical countries [95] might be due to a mechanism similar to that in the Asian community,

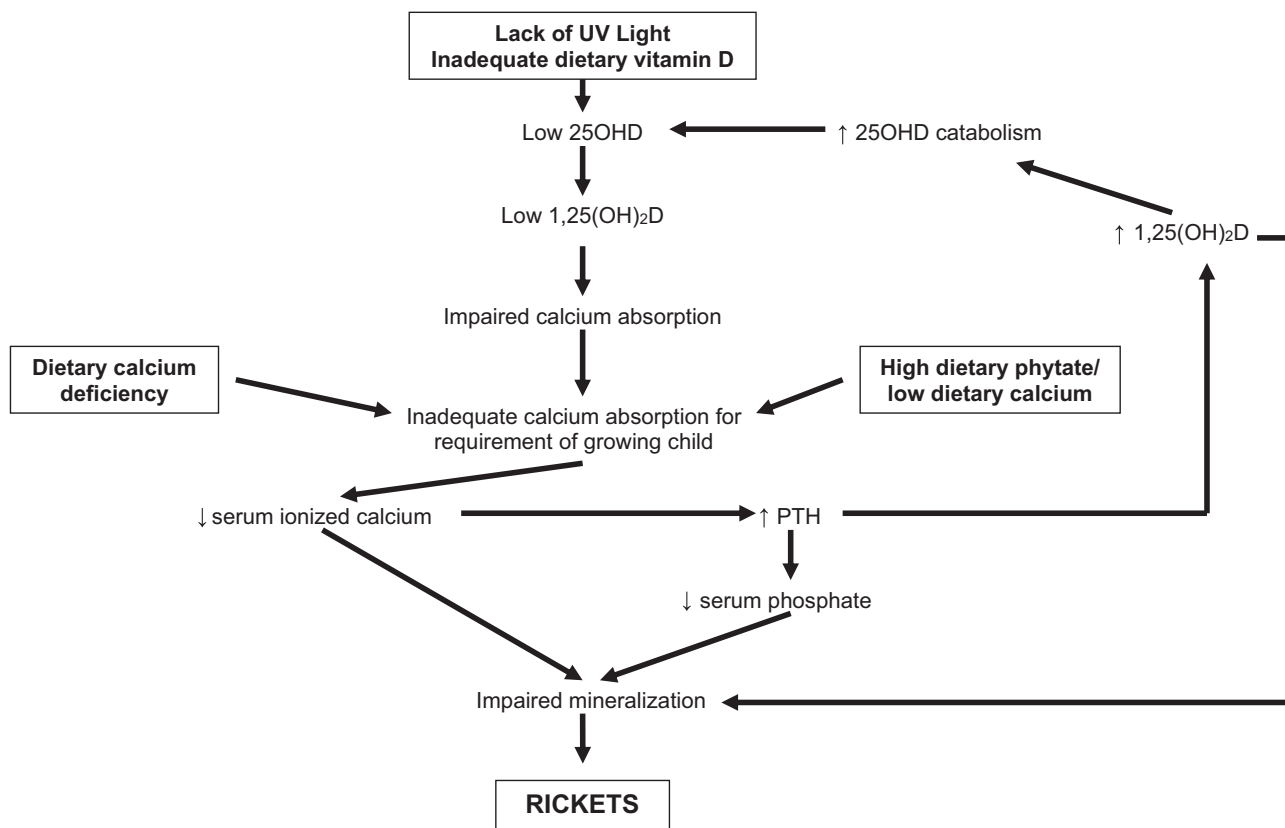

**FIGURE 63.9** An algorithmic approach to the diagnosis and management of the metabolic bone disease of prematurity. Adapted with permission from Ref. [397].

while osteomalacia in Bedouin adults in the Middle East reflects mainly dietary calcium deficiency [421].

A number of studies have highlighted the complex interaction between vitamin D and calcium intakes in the pathogenesis of nutritional rickets in children. A review of 43 patients diagnosed as having nutritional rickets in New Haven, Connecticut, found low 25(OH) D levels in only 22%, and the majority of infants had been weaned onto diets with minimal dairy content [117]. The authors concluded that low dietary calcium

intakes probably played a major role in the pathogenesis of the disease. Similar findings are reported from India, where it is suggested that low dietary calcium intakes were responsible for rickets in young children, while vitamin D deficiency played a major role in adolescents [317]. A recent reanalysis of data obtained from a large randomized controlled trial of the treatment of children with active nutritional rickets in Nigeria [275] has highlighted the synergistic effects of low dietary calcium intakes and a poor vitamin D status on the risk of

**FIGURE 63.10** The pathogenesis of nutritional rickets in children emphasizing the common final pathways of both dietary calcium deficiency and vitamin D deficiency resulting in hypocalcemia and hypophosphatemia and impaired mineralization.

developing rickets in LMIC [137] (Figs. 63.8 and 63.11). Despite the clear evidence of the importance of these two factors in the pathogenesis of active rickets, the study was unable to tease out the factors that resulted in the poorer vitamin D status of affected children compared with that of community controls, or how some children were protected from developing rickets despite being on very low calcium intakes.

## 14. Conclusion

Despite readily accessible and effective means to eradicate nutritional rickets globally, the disease remains a major public health problem in many countries, not only in temperate regions of the world but also in tropical and subtropical countries. In many developed countries, the promotion of exclusive breastfeeding during the first 6 months of life and the concerns about the long-term effect of sunlight exposure during this period have exacerbated the risks of vitamin D deficiency in the young infant. In some subtropical countries, social customs play an important role in preventing adequate vitamin D status not only in the young

infant but also in the pregnant and lactating mother. In a number of developing countries, low dietary calcium intakes appear to play a major role in the pathogenesis of rickets in older children. Recent studies have helped to provide an all embracing concept of the interaction of vitamin D and calcium intakes in the pathogenesis of nutritional rickets. Further, the rapidly improving survival of very-low-birth-weight infants has highlighted the role of a lack of adequate dietary phosphorus intakes in the pathogenesis of metabolic bone disease of prematurity. In older infants and children, dietary phosphorus deficiency is a rare and unlikely cause of nutritional rickets due to the ubiquitous nature of phosphorus in foods; however, the special needs of the very-low-birth-weight infant have focused attention on metabolic bone disease of prematurity being a progressively important and preventable form on nutritional rickets.

There remains a need for international agencies to place the eradication of vitamin D deficiency and low calcium intakes among young children in many parts of the world as a priority. Nutritional rickets not only leads to an increased infant mortality but also has long-term sequelae.

**FIGURE 63.11** 25-Hydroxyvitamin D levels in Nigerian children with untreated nutritional rickets believed to be mainly due to dietary calcium deficiency and age- and sex-matched controls from the same community. Mean 25-hydroxyvitamin D is significantly lower in the rachitic subjects, but its concentration is above the generally recognized cut point for vitamin D deficiency of 30 nmol/L. *Reproduced with permission from Ref. [137].*

# Clinical disorders of phosphate homeostasis

Eva S. Liu<sup>1,2,3</sup> and Harald Jüppner<sup>2,3</sup>

<sup>1</sup>Division of Endocrinology, Diabetes, and Hypertension, Brigham and Women's Hospital, Boston, MA, United States

<sup>2</sup>Endocrine Unit, Massachusetts General Hospital, Boston, MA, United States <sup>3</sup>Harvard Medical School, Boston, MA, United States

## OBJECTIVES

- To describe the molecular and hormonal regulation of phosphate homeostasis.
- To describe the clinical presentation, genetic basis, and treatment of disorders of phosphate homeostasis, including those that present with hypophosphatemia or hyperphosphatemia.

## 1. Introduction

Extracellular phosphate is a critical component of the skeleton that plays an important role in modulating skeletal processes such as growth plate maturation and skeletal mineralization. Phosphate homeostasis is regulated by dietary intake and the regulators of mineral ion homeostasis, namely parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF23). Disorders disrupting phosphate homeostasis have resulted in a greater understanding of the molecular regulation of phosphate balance as well as the hormones that modulate phosphate homeostasis.

## 2. Phosphate homeostasis

Extracellular phosphate is an important component of the skeleton. Growing children have positive phosphate balance to support skeletal growth, while adults have a phosphate balance of zero. Osteomalacia in adults results if phosphate balance is negative. Phosphate accounts for

about 0.6% of the body weight at birth, and about 1% of body weight in the adult [1]. 85% of phosphate is in the skeleton and teeth, with the remaining 15% in the soft tissue and extracellular fluid [2].

In plasma, phosphate exists in either the inorganic or the organic form, which consists primarily of phospholipids and phosphate esters [3]. The total concentration of phosphate in plasma is about 14 mg/dL, of which 4 mg/dL is inorganic phosphate (Pi). Of phosphate, which is routinely measured in the clinical setting, namely Pi, 10%–15% is protein-bound and the remainder is filtered at the renal glomeruli and is usually complexed with sodium, calcium, or magnesium.

Sodium-dependent phosphate absorption in the small intestine is predominantly regulated by the sodium-dependent phosphate cotransporter type IIb (NPT2b, *SLC34A2*), with a minor contribution by the type III sodium-dependent phosphate cotransporters Pit1 and Pit2 [4]. Phosphate is then filtered by the kidney, where it is either reabsorbed or excreted depending on the requirements of the organism. About 60%–65% of dietary intake of phosphate is absorbed by the small intestine, where the higher the dietary load, the larger the amount of phosphate that is absorbed [1]. If an adult is in zero phosphate balance, the intestinal absorption of phosphate is equal to the amount of phosphate excreted by the kidney. In growing children, the net amount of phosphate excreted is less than the amount absorbed by the small intestine, thus resulting in positive phosphate balance [5]. Because serum phosphate concentrations vary throughout the day depending on dietary phosphate intake and oral phosphate supplementation, collection of a fasting blood sample is preferred for clinical analysis.

The proximal tubule of the kidney is the major site of phosphate reabsorption, with about 70% of the filtered load being reabsorbed in the proximal convoluted tubule, 10% in the proximal straight tubule, and <10% in the distal segments of the nephron [6]. Renal reabsorption of phosphate progressively increases as the filtered load increases, until a maximum tubular reabsorption rate for phosphate (TmP) is reached, after which phosphate excretion increases in proportion with the filtered load. The TmP can vary for the same person and between people due in part to the variation in GFR; therefore, TmP/GFR (maximum tubular reabsorption of phosphate per unit volume of GFR) is used as the quantitative estimate of renal tubular phosphate reabsorption [2].

Transport of phosphate across the renal tubule cells involves uptake of phosphate at the brush border apical membrane, translocation across the cell, and efflux at the basolateral membrane [7]. Renal reabsorption of phosphate is mediated by the brush border sodium-dependent ( $\text{Na}^+$ ) phosphate ( $\text{Pi}$ ) transporters, which depend on the  $\text{Na}^+/\text{K}^+$ -dependent ATPase on the basolateral membrane. There are three classes of  $\text{Na}/\text{Pi}$  cotransporters. Type I  $\text{Na}/\text{Pi}$  cotransporter (NPT1, *SLC17A1*) is expressed on the renal brush border membrane of the proximal tubule and can regulate the transport of  $\text{Pi}$  as well as other ions like chloride [8]. Interestingly, neither dietary phosphate nor PTH alters NPT1 protein or mRNA expression. Besides transporting phosphate, NPT1 also exports anions and urate.

Type II  $\text{Na}/\text{Pi}$  cotransporters include three highly homologous isoforms, including type IIa (NPT2a, *SLC34A1*), type IIc (NPT2c, *SLC24A3*), and type IIb (NPT2b, *SLC34A2*). NPT2a and NPT2c are exclusively expressed on the renal proximal tubule brush border membrane, while NPT2b is expressed in several tissues, including lung and the small intestine, but not the kidney [9–12]. NPT2a and NPT2c have eight membrane-spanning segments, where human NPT2a comprises 635 amino acids and its gene is located on chromosome 5q35, while human NPT2c comprises 599 amino acids and its gene is located on chromosome 9q34 [13]. In mice, Npt2c is approximately one order of magnitude less abundantly expressed than Npt2a [3].

Type III  $\text{Na}/\text{Pi}$  cotransporters are cell surface retroviral receptors (gibbon ape leukemia virus [Glv-1, Pit-1, *SLC20A1*] and murine amphotropic virus [Ram-1, Pit-2, *SLC20A2*]) that are ubiquitously expressed [14,15]. They are localized to all segments of the nephron at the basolateral membrane and mediate cellular phosphate balance.

## 2.1 Regulation of phosphate homeostasis

Dietary intake as well as hormones, particularly parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF23), play important roles in regulating phosphate

balance. Exposure to a low phosphate diet dramatically reduces urinary phosphate excretion [16], which was shown in rodents to be due to increasing Npt2a protein, but not NPT2a mRNA expression in the renal proximal tubule [17,18]. Subsequent studies demonstrated that low dietary phosphate does not activate NPT2a promoter activity [19]. In complementary studies, exposure to high phosphate diet results in the internalization of NPT2a protein and subsequent degradation by lysosomes via a microtubule-dependent process [20]. Likewise, a low phosphate diet increases NPT2c protein on the renal proximal tubular apical membrane, while NPT2c protein expression is decreased with exposure to high phosphate diet [21,22] (Fig. 64.1).

PTH regulates phosphate homeostasis by promoting the rapid internalization of NPT2a and its subsequent lysosomal degradation [23,24]. PTH binds to PTH/PTHrP receptors (PTHr1) on the basolateral membrane to increase cAMP signaling and to activate protein kinase A (PKA) or protein kinase C (PKC), while binding to receptors on the apical membrane is thought to activate only PKC [25]. NHERF2 interacts with the PTHr1 at the apical brush border membrane to coordinate the PTH-mediated activation of phospholipase C and inhibition of adenylyl cyclase through stimulation of inhibitory G proteins [26]. The PKA and PKC pathways may both activate ERK/MAPK signaling pathway to induce the PTH-mediated internalization of NPT2a [27,28]. Accessory proteins such as AKAP79 and RAP have been shown to play an important role in PTH-mediated NPT2a endocytosis [29,30]. Humans with NHERF1 mutations present with hypophosphatemia and renal phosphate wasting [31,32]; however, these findings are not universally observed [33]. It was demonstrated that NHERF1 stabilizes NPT2a on the membrane surface and can also prevent desensitization of the PTH signal [34].

A key regulator of phosphate balance is the hormone FGF23, which consists of 251 amino acid residues, including a signal peptide comprising 24 amino acids [35]. Referred to as a “phosphatonin,” FGF23 is a secreted FGF that modulates phosphate homeostasis. It was identified through genetic linkage studies to determine the cause of autosomal dominant hypophosphatemic rickets (ADHR), which resulted in the identification of mutations affecting either Arg176 or Arg179 that render FGF23 resistant to cleavage [36]. Especially in humans and mice on a low iron diet, the mutant FGF23 causes hypophosphatemia due to renal phosphate wasting [37,38]. FGF23 was also isolated from tumors that induce osteomalacia (TIO) because of abundant FGF23 expression [35] that is most likely triggered by expression of a chimeric FGFR/fibronectin protein [39]. Patients with this acquired disorder present with low serum phosphate levels and thus clinical

**FIGURE 64.1** Dietary phosphate regulates NPT2a and NPT2c: NPT2a and NPT2c are expressed on the brush border of the proximal renal tubule. Male Wistar rats were fed a low-phosphate diet for 2 days and then transitioned to one of three groups: chronic low-phosphate diet (CLP) or acute high-phosphate diet for 4 h (AHP 4 h) or 6 h (AHP 6 h). Immunohistochemical analysis of renal proximal tubular cells shows that the NPT2a and NPT2c cotransporters colocalize to the apical membrane (A–C) when rats are fed a low-phosphate diet. Administration of high-phosphate diet–induced translocation of NPT2a and NPT2c to intracellular compartments (D–I). *Figure modified from Ref. [21].*

symptoms that are similar to those observed in hypophosphatemic rickets. Administration of FGF23 to mice decreases serum phosphate and  $1,25(\text{OH})_2\text{D}$  levels, and it increases urinary phosphate losses [40,41]. Mice with vastly elevated FGF23 levels due to transplantation of cell lines stably expressing FGF23, or by expressing FGF23 transgenically under the control of different promoters, exhibit similar phenotypes with hypophosphatemia due to renal phosphate wasting, osteomalacia/rickets, and decreased  $1,25(\text{OH})_2\text{D}$  levels [42,43]. The opposite findings are encountered in FGF23-null mice that manifest hyperphosphatemia, increased serum  $1,25(\text{OH})_2\text{D}$  levels, and thus hypercalcemia [44,45]. FGF23 downregulates expression of *Cyp27b1*, the gene encoding the  $1\alpha$ -hydroxylase, and it upregulates *Cyp24a1*, the gene encoding an enzyme that metabolizes  $1,25(\text{OH})_2\text{D}$ , thus explaining the decreased circulating levels of  $1,25(\text{OH})_2\text{D}$  when FGF23 levels are elevated.

FGF23 undergoes O-linked glycosylation at Thr178 and probably other sites, which reduces cleavage at the RXXR site (residues 176–179) by a subtilisin-like proprotein convertase [46]. In contrast, cleavage is enhanced when

phosphorylation by FAM20C occurs at Ser180, which in turn reduces O-glycosylation at Thr178 [47]. Cleavage at the RXXR site generates a C-terminal 12 kDa fragment from the 32 kDa intact, glycosylated FGF23 [48]. FGF23 is expressed at low levels in a variety of tissues, including heart, liver, thymus, and brain [35,36]. However, it is predominantly expressed in bone, specifically osteocytes and at lower levels in osteoblasts [35,49]. Thus, osteoblast- or osteocyte-specific ablation of FGF23 results in a 40%–50% reduction in circulating FGF23 levels [50]. Loss-of-function variants in DMP1 [51], PHEX [52], FAM20C [53], and ENPP1 [54] lead to high circulating levels of FGF23 in mice and humans. Furthermore, it was recently shown that Glycerol-3-phosphate, a downstream product of glycolysis, is locally converted to lysophosphatidic acid (LPA), which stimulates FGF23 production. In vitro studies demonstrated that  $1,25(\text{OH})_2\text{D}$  in combination with LPA is required to increase FGF23 expression and that LPA increases VDR binding to the FGF23 promoter, suggesting that  $1,25(\text{OH})_2\text{D}$  action is downstream of LPA [55]. In the presence of the cofactor Klotho, FGF23 binds to FGFR1 with high affinity [56]. FGFR1 is the

predominant receptor for FGF23 action, with FGFR4 likely playing a minor role in the phosphaturic effect of FGF23 [57,58].

## 2.2 Phosphate and vitamin D metabolism

Dietary phosphate and serum phosphate concentration are important in the regulation of  $1,25(\text{OH})_2\text{D}$ . Acute hypophosphatemia induced in rats by dietary restriction increases the  $1\alpha$ -hydroxylase activity and thus the synthesis of  $1,25(\text{OH})_2\text{D}$  [59]. Likewise, dietary phosphate restriction in humans increases serum  $1,25(\text{OH})_2\text{D}$  levels, while phosphate supplementation decreases serum  $1,25(\text{OH})_2\text{D}$  concentrations [60]. Murine studies have furthermore demonstrated that dietary phosphate restriction increases CYP27B1 mRNA and the encoded  $1\alpha$ -hydroxylase protein in the renal proximal tubule by six- to eightfold increase [61]. Phosphate restriction furthermore decreases renal 24-hydroxylase activity and expression, thereby decreasing degradation of  $1,25(\text{OH})_2\text{D}$  [62,63]. Conversely, treatment of vitamin D-deficient rats with  $1,25(\text{OH})_2\text{D}$  enhances NPT2a mRNA expression and protein in the renal brush border membrane [64]. While the decrease in PTH that follows  $1,25(\text{OH})_2\text{D}$  administration could explain increased NPT2a levels, it has been reported that  $1,25(\text{OH})_2\text{D}$  can directly enhance NPT2a promoter activity and protein level in the kidney [64].

## 2.3 Clinical symptoms of hypophosphatemia and hyperphosphatemia

Moderate to severe hypophosphatemia can be associated with clinical symptoms [65]. Although chronic hypophosphatemia is usually asymptomatic, acute severe hypophosphatemia concurrent with phosphate depletion can lead to significant clinical manifestations. Low serum phosphate is commonly a consequence of chronic alcoholism [66,67]. A combination of other factors, including inappropriate phosphaturia, gastrointestinal losses, hyperventilation, or infusion of dextrose-containing fluids, can contribute to the hypophosphatemia in alcoholism [65].

Hematologic consequences of hypophosphatemia may include hemolysis or leukocyte dysfunction. Adequate phosphate levels are necessary to maintain ATP levels in red blood cells and leukocytes [68]. The fall in ATP levels from hypophosphatemia has been associated with decreased life span of red blood cells and can cause hemolytic anemia [69–71]. It has been reported that decreased ATP levels in leukocytes in hypophosphatemic patients can impair cell function, notably chemotaxis and phagocytosis [72,73].

Compromised respiratory function can also be due to hypophosphatemia. Respiratory muscle weakness,

including impaired diaphragm function, can occur with low phosphate levels [74,75]. In hospitalized patients who had low phosphate levels, improvement in respiratory muscle function was observed with phosphate repletion. A decrease in myocardial function has also been noted with severe acute hypophosphatemia [76,77]. However, a study of pediatric patients with chronic hypophosphatemia from X-linked hypophosphatemia (XLH) demonstrated no alteration in left ventricular function [78]. Central and peripheral nervous system dysfunction has been reported in patients with acute severe hypophosphatemia after developing refeeding syndrome [79,80]. Patients may manifest with irritability and muscle weakness and progress to confusion or coma [80,81].

Hyperphosphatemia is generally asymptomatic. A significant consequence of elevated phosphate levels is hypocalcemia due to the precipitation of calcium-phosphate deposits in soft tissue. These ectopic calcifications have been observed in renal failure, hypoparathyroidism, pseudohypoparathyroidism, or tumoral calcinosis, all of which are disorders associated with hyperphosphatemia. Biochemical consequences of elevated phosphate levels can be secondary hyperparathyroidism or the suppression of production of  $1,25(\text{OH})_2\text{D}$ .

## 3. Disorders of phosphate homeostasis

There are many disorders that affect phosphate homeostasis, including inherited syndromes as well as acquired disorders (Table 64.1). In recent years, the genetic cause for many of these diseases has been identified (Fig. 64.2). The aberrant genes are often lead to abnormalities in FGF23 function or phosphate transport.

### 3.1 Fanconi syndrome

In Fanconi syndrome, disruption to the function of the proximal renal tubule by genetic or secondary causes results in hypophosphatemia, proximal renal tubular acidosis, and renal losses of amino acids, glucose, bicarbonate, and phosphate. The hypophosphatemia was thought to be a consequence of inappropriately low levels of serum  $1,25(\text{OH})_2\text{D}$  (Fanconi syndrome, type 1) [82,83]. Affected individuals can present with clinical findings consistent with osteomalacia and rickets, with bowing of the legs and short stature. Histomorphometric analyses show decreased cancellous bone volume and increased osteoid [83]. Treatment involves supplementation with phosphate and/or calcitriol. Rare inherited disorders, which may be complicated by Fanconi syndrome, include cystinosis, Wilson's disease, Lowe syndrome, type I glycogen storage disease, or galactosemia. The majority of cases have an acquired form of Fanconi syndrome due to secondary causes

that may include burn injuries, exposure to certain medications or toxic metals, or a variety of other conditions such as multiple myeloma or amyloidosis [83]. Tenofovir, an anti-retroviral medication used for treatment of HIV/AIDS, is well documented to be associated with hypophosphatemia due to development of Fanconi syndrome [84]. Patients infected with acute respiratory syndrome coronavirus (SARS-CoV-2), who have severe disease requiring hospitalization, may have a higher incidence of hypophosphatemia associated with acute kidney injury. It is hypothesized SARS-CoV-2 infection of the proximal renal tubules may lead to Fanconi syndrome [85].

An autosomal recessive form of renal Fanconi syndrome was described in 1988 in two siblings that were products of a consanguineous marriage. Both had

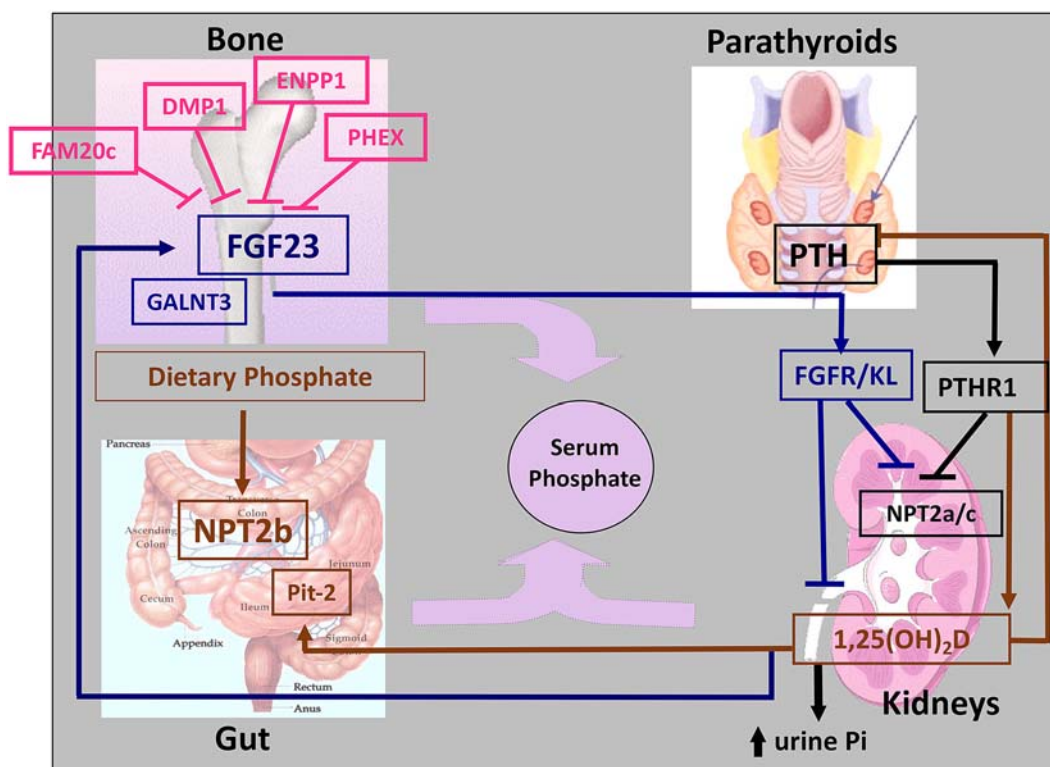

marked hypophosphatemia and elevated 1,25(OH)<sub>2</sub>D levels, associated with rickets, growth retardation, and skeletal deformities [86]. At the ages of 39 and 43 years, when a homozygous loss-of-function mutation was found in *SLC34A1* that encodes NPT2a, both siblings had only mild hypophosphatemia, normal 1,25(OH)<sub>2</sub>D levels, and no increase in urinary calcium excretion, yet had impaired renal function [87]. Recently, numerous other homozygous or compound heterozygous NPT2a mutations were described in several infants with severe hypophosphatemia, decreased TmP/GFR, as well as severe hypercalcemia and hypercalciuria caused by elevated 1,25(OH)<sub>2</sub>D levels [88].

### 3.2 Genetic hypophosphatemic syndromes of excess FGF23

#### 3.2.1 Hypophosphatemic rickets—X-linked hypophosphatemia

X-linked hypophosphatemia (XLH) is the most frequent inherited form of hypophosphatemic rickets, where the incidence is reported at 1:20,000 [89]. It is inherited in an X-linked dominant pattern with complete penetrance, where males and females are affected equally. The phenotype can vary widely even in the same family. Diagnosis of XLH can be delayed until adulthood due to lack of awareness of phosphate levels or expression of a mild phenotype. Affected individuals often present with rickets and osteomalacia, causing short stature and bowed legs. The growth plates are abnormally expanded; therefore, the metaphyses of long bones are widened [90]. There is discordant growth between the long bones and the torso, with the growth retardation being more apparent in the long bones [91]. Clinical presentation of XLH may also include dental abscesses due to defective dentin or enamel, and cranial synostosis [92,93]. Adults may manifest with pseudo-fractures, osteoarthritis, osteophytes, or enthesopathy, which is the abnormal mineralization of the bony insertion sites of tendons and ligaments [94,95]. Patients may also report muscle weakness or cramping, though many XLH patients are often asymptomatic from the hypophosphatemia [2]. As adults, XLH patients also report tinnitus and conductive hearing loss. Mice with XLH similarly have conductive hearing loss, which is associated with hypomineralization of the auditory ossicles [96].

Most individuals affected by XLH have elevated (or inappropriately normal) serum FGF23 levels, thus explaining their hypophosphatemia and renal phosphate wasting, as well as their low or inappropriately normal 1,25(OH)<sub>2</sub>D levels caused by suppression of the renal 1 $\alpha$ -hydroxylase [49]. Additional biochemical characteristics of XLH include normal serum calcium

**FIGURE 64.2** Molecular pathways underlying genetic disorders of phosphate homeostasis: Dietary phosphate is absorbed in the gut by NPT2b and filtered by the kidney. In the small intestine, phosphate transport is predominantly regulated by NPT2b. 1,25(OH)<sub>2</sub>D increases Pit-2 expression in the small intestine, which also enhances phosphate absorption, and feeds back to decrease PTH production by the parathyroid glands. Pit-1 is expressed in the small intestine; however, a role for this transporter in phosphate absorption has not yet been defined. PTH binds to the PTHR1 to reduce NPT2a and NPT2c protein levels, resulting increased renal loss of phosphate. FGF23 is predominantly expressed in bone and binds to the FGFR with  $\alpha$ -Klotho (KL) as coreceptor in the kidneys. It thus increases, like PTH, urine phosphate excretion by decreasing renal proximal tubule expression of NPT2a and NPT2c. FGF23 furthermore stimulates 24-hydroxylase expression, and it reduces the 1- $\alpha$ -hydroxylase. The combined net effects of the actions of FGF23 in proximal renal tubules are decreased serum levels of phosphate and 1,25(OH)<sub>2</sub>D. FGF23 expression is down-regulated by PHEX, DMP1, ENPP1, and FAM20C. Heterozygous loss-of-function mutations in PHEX cause X-linked hypophosphatemia (XLH), while homozygous loss-of-function mutations in DMP1, ENPP1, or FAM20C lead to autosomal recessive hypophosphatemic rickets (ARHR). Mutations at the cleavage site of FGF23 increase circulating intact FGF23 and therefore cause autosomal dominant hypophosphatemic rickets (ADHR), especially in the presence of iron deficiency. The different forms of hyperphosphatemic familial tumoral calcinosis are caused by homozygous mutations in GALNT3, FGF23, or  $\alpha$ -Klotho. GALNT3 mediates the glycosylation and stabilization of FGF23, while  $\alpha$ -Klotho is the coreceptor required for FGF23 action in the kidney. Homozygous or compound heterozygous mutations in NPT2a lead to renal Fanconi syndrome or a more severe phosphate-wasting disorder associated with hypercalcemia, previously referred to as idiopathic infantile hypercalcemia. Homozygous or compound heterozygous mutations in NPT2c cause hereditary hypophosphatemic rickets with hypercalciuria (HHRH).

and 25(OH)D levels, and serum PTH levels that are frequently elevated even before initiation of oral phosphate supplements [97,98] (Table 64.2).

A murine equivalent of human XLH is the Hyp mouse, which has a deletion in the 3' region of the PHEX gene; [99] PHEX mutations have also been identified in other mice with XLH, including Gy [100], Ska1 [101], Hyp-Duk, Hyp-2J [102], Pug [103], and Kbus/Idr [104] mouse models. The Hyp mouse has a phenotype that is very similar to that of humans with XLH, namely hypophosphatemic rickets due to renal phosphate wasting, low serum phosphate and 1,25(OH)<sub>2</sub>D levels, and consistently elevated serum FGF23. As a result of the increased FGF23 action, expression of 1 $\alpha$ -hydroxylase is reduced, while 24-hydroxylase expression is

increased, thus leading through two mechanisms to a decrease in circulating 1,25(OH)<sub>2</sub>D levels [49].

### 3.2.1.1 Pathophysiology of XLH

XLH is caused by inactivating mutations in the PHEX gene, which is located on chromosome Xp22.1 [105]. A large variety of different mutations throughout the PHEX gene have been described, including missense, frameshift, nonsense, duplication, and insertion mutations [106,107]. A database of mutations identified in PHEX can be found at the website [www.db.mcgill.ca](http://www.db.mcgill.ca). PHEX is expressed in several tissues such as lung, brain, and teeth, but it is predominantly expressed in bone, specifically in osteocytes and osteoblast cell types [52,108]. The PHEX protein shows significant homology

to the M13 family of zinc metallopeptidases, which include neutral endopeptidase neprilysin (NEP), endothelin-converting enzyme 1 (ECE-1 and 2), and the Kell antigen [108,109]. This group of proteins are type II integral membrane glycoproteins that have a short N-terminal cytoplasmic domain, a single transmembrane hydrophobic region, and a large extracellular domain. The direct target of PHEX endopeptidase activity currently remains unknown. It was initially thought that PHEX cleaves FGF23 [110]. However, it has since been determined that while FGF23 is overexpressed in the setting of PHEX mutations, its cleavage is not altered by these mutations [110,111]. Bones in Hyp mice have increased expression of MEPE (matrix extracellular phosphoglycoprotein), which contains an acidic, serine, and aspartic acid-rich motif (ASARM). Studies demonstrated that PHEX binds to and cleaves the triphosphorylated ASARM motif in proteins like MEPE to block their inhibition of mineralization [112].

Investigations into the pathogenesis of XLH have confirmed the roles of PHEX and FGF23 in developing the rachitic phenotype. Conditional ablation of PHEX in osteoblasts (using the osteocalcin promoter) resulted in osteomalacia with elevated serum FGF23 levels, hypophosphatemia, and decreased renal Npt2a expression [52]. However, while overexpression of PHEX under the control of the pro- $\alpha$ 1(I) collagen promoter in Hyp mice improved the skeletal mineralization, it did not normalize serum phosphate levels [113]. Moreover, overexpression of FGF23 under the  $\alpha$ 1(I) collagen promoter recapitulated the hypophosphatemic rickets phenotype, including decreased renal expression of Npt2a, hypophosphatemia, and phosphaturia, and a decrease in skeletal mineralization with growth retardation [114]. Deletion of FGF23 from Hyp mice reversed the low serum phosphate and 1,25(OH)<sub>2</sub>D levels, but

did not normalize skeletal mineralization or growth, supporting a role for FGF23-specific actions on these processes [49]. A few studies have provided in vitro evidence that FGF23 may suppress mineralization independent of its effect on phosphate homeostasis. Overexpression of FGF23 in rat calvarial osteoblasts resulted in decreased mineralization and nodule formation, while there was decreased bone formation in parietal bone organ culture [115]. Treatment of wild-type calvarial osteoblasts furthermore suppressed formation of mineralized nodules in vitro [116].

The defect in skeletal mineralization in the XLH phenotype may not be attributable to just the mineral ion and hormone abnormalities. There is an accumulation of the mineralization inhibitor osteopontin, a target of PHEX, in the extracellular matrix of Hyp bone. Deletion of osteopontin in the Hyp mice modestly improved skeletal mineralization [117]. Furthermore, implantation of Hyp osteoblasts into wild-type mice reduced, but did not normalize the osteoid thickness and volume of the transplants, thus suggesting an intrinsic osteoblast defect in Hyp mice [118]. When wild-type osteoblasts were grown in medium with phosphate concentrations similar to those of serum levels in wild-type mice, alkaline phosphatase activity increased. In contrast, Hyp osteoblasts failed to respond to 1,25(OH)<sub>2</sub>D treatment when exposed to the same phosphate concentration, thus demonstrating that Hyp osteoblasts have an abnormal response to 1,25(OH)<sub>2</sub>D [119].

Studies have furthermore demonstrated the critical importance of extracellular phosphate for normal growth plate maturation [120–122]. The murine model of XLH (Hyp mouse) shows an expansion of growth plates that is similar to that of mice with ablation of the vitamin D receptor and mice fed a low phosphate diet. These mice all have hypophosphatemia and

**FIGURE 64.3** Fam20C phosphorylates FGF23: FAM20C is a kinase located in the endoplasmic reticulum/Golgi network that phosphorylates proteins with the SXE motif. FGF23 is phosphorylated by FAM20C on S180, which is adjacent to the 176-RXXR-179 SPC cleavage site. Phosphorylation of FGF23 on S180 (shown as pS) reduces glycosylation of the T178 by GALNT3 (red cross), therefore rendering FGF23 more susceptible to cleavage by a furin-like enzyme (red arrow), resulting in the generation of increased levels of C-terminal FGF23 fragments. Conversely, homozygous Fam20C mutations prevent phosphorylation at S180, thus enhancing glycosylation and stability of FGF23, consequently promoting hypophosphatemia. *Modified from Ref. [47].*

growth plate expansion, along with a decrease in apoptotic hypertrophic chondrocytes [120]. Erk1/2 activation, which is necessary for hypertrophic chondrocyte cell death, is decreased in the growth plate [122]. PTHrP action is also thought to be necessary for the growth plate expansion observed in low phosphate conditions: mice heterozygous for the ablation of PTHrP did not develop the anticipated growth plate expansion when fed a low phosphate diet [123]. Since mice and humans with XLH have elevated serum PTH levels and Hyp mice have increased expression of PTHrP at the periaricular surface, the actions of both ligands may contribute to the abnormal growth phenotype.

In addition to its ability to increase serum calcium and phosphate levels, 1,25(OH)<sub>2</sub>D is also important for growth and skeletal mineralization and structure in XLH. The excess FGF23 in XLH suppresses 1 $\alpha$ -hydroxylase and increases vitamin D 24-hydroxylase expression to decrease levels of 1,25(OH)<sub>2</sub>D. Ablation of vitamin D 24-hydroxylase (*Cyp24a1*) in Hyp mice or mice overexpressing FGF23 resulted in significant amelioration of the osteomalacia and rachitic changes observed with XLH despite persistent hypophosphatemia [124]. Although serum 1,25(OH)<sub>2</sub>D levels decreased, there was an increase in local tissue production of 1,25(OH)<sub>2</sub>D [124]. In addition, treatment of Hyp mice with calcitriol alone was sufficient to improve growth, growth plate maturation, skeletal microarchitecture, and dentoalveolar mineralization; in fact, growth was improved more significantly with 1,25(OH)<sub>2</sub>D than treatment with the anti-FGF23 blocking antibody despite increased serum levels of FGF23

[89,125]. Administration of calcitriol alone also restored Npt2a expression in the kidney [89] (Fig. 64.3).

Hyp cortical bone is characterized by dramatically impaired osteocyte lacunocanicular organization with enlarged lacunae and sparse canaliculi. Treatment of Hyp mice with either calcitriol alone or the anti-FGF23 antibody normalizes osteocyte lacunar size and partially restores canicular structure [126]. Deletion of the vitamin D receptor (VDR) in osteocytes similarly results in enlarged osteocyte lacunae and impaired canicular structure, thus suggesting that impaired 1,25(OH)<sub>2</sub>D signaling in Hyp mice contributes to the osteocyte lacunocanicular abnormalities (Fig. 64.4) [127]. While the pathophysiology underlying the paradoxical mineralization of the bone–tendon attachment sites, called enthesopathy, observed in XLH is poorly understood, recent studies demonstrate that cells in the Hyp entheses have increased alkaline phosphatase activity and enhanced bone morphogenic protein (BMP) and Indian hedgehog (IHH) signaling, both of which regulate chondrogenesis. Treatment of Hyp mice with either calcitriol alone or the anti-FGF23 blocking antibody prevents enthesopathy in Hyp mice, also pointing to a role for impaired 1,25(OH)<sub>2</sub>D action in XLH enthesopathy [128]. Taken together, these studies support an important role for 1,25(OH)<sub>2</sub>D in the pathogenesis of the skeletal phenotype observed in XLH.

### 3.2.1.2 Treatment of XLH

Treatment for XLH in children is predominantly aimed at improving their growth, to minimize rickets/

**FIGURE 64.4** Decreased 1,25(OH)<sub>2</sub>D action contributes to the impaired lacunocanalicular structure observed in bones from mice with XLH (Hyp): H&E and silver stain of day 30 tibia in Hyp mice and mice lacking the vitamin D receptor (VDR) in osteocytes (VDR<sup>f/f</sup>;DMP1<sup>Cre+</sup>), with wild-type (WT) and VDR<sup>f/f</sup>;DMP1<sup>Cre-</sup> controls. The lacunae are visualized by H&E stain, and lacunar area per osteocyte (Lac.Ar/ocyt) is quantitated by histomorphometry. The canalicular network is visualized by silver stain and canalicular density (#canaliculi/ocyt) quantitated. Both Hyp and VDR<sup>f/f</sup>;DMP1<sup>Cre+</sup> tibiae have enlarged lacunae and decreased canalicular density compared with controls, indicating that an impaired production of 1,25(OH)<sub>2</sub>D contributes to the osteocyte lacunocanalicular network abnormalities observed in Hyp mice. \* =  $P < .05$  versus WT, # =  $P < .05$  versus Hyp, a =  $P < .05$  versus VDR<sup>f/f</sup>;DMP1<sup>Cre-</sup>. Figure modified from Ref. [127].

osteomalacia, and thus to prevent bowing. Children with XLH are often treated with conventional therapy with a combination of oral phosphate, given multiple times per day, and calcitriol, from the time of diagnosis until active growth has stopped. However, these pediatric patients are increasingly being treated with a humanized antibody targeting FGF23, named burosumab (Crysvita), which is FDA approved for the treatment of children and adults with XLH. Administration of a combination phosphate and calcitriol therapy can decrease alkaline phosphatase levels and improve, but not normalize skeletal growth and mineralization [90,97]. Serum phosphate levels do not normalize with conventional therapy because of persistent renal phosphate losses due to elevated circulating FGF23 levels. In fact, treatment of XLH patients with this combination therapy further increases serum FGF23 levels [129]. In children whose growth retardation is refractory to standard therapy, adjuvant therapy with growth hormone has improved growth velocity in some studies [130,131]. However, outcomes with growth hormone therapy are variable since some studies reported only transient or no improvement in biochemical parameters, lack of improved growth velocity, and potential worsening of skeletal complications [91,131–133]. Unlike children, most adults with XLH are only treated if they have active osteomalacia, are

undergoing orthopedic procedures, or have symptoms such as bone pain or muscle cramps and fatigue.

Complications of conventional therapy may include hypercalciuria or hypercalcemia from calcitriol therapy [134]. Also, the doses of phosphate (and compliance with this medication) and calcitriol are thought to be correlated with the development of nephrocalcinosis, which can lead to compromised renal function [135]. Phosphate therapy alone leads to secondary and tertiary hyperparathyroidism, requiring parathyroid surgery [136]. Therefore, calcitriol is normally added to suppress PTH synthesis and secretion. In addition, calcimimetics such as cinacalcet have been reported to decrease PTH levels in XLH patients, thus decreasing the PTH-dependent urinary phosphate losses [137]. Because of the toxicities associated with standard therapy, close monitoring of biochemical parameters in actively treated XLH is needed. It is also unclear if conventional treatment with oral phosphate and low doses of calcitriol therapy can prevent or treat complications of XLH such as enthesopathy, osteoarthritis, or dental abscesses. In an observational cross-sectional study, therapy with combination calcitriol (1,25(OH)<sub>2</sub>D) and oral phosphate in adults with XLH did not alter the number of entheses sites affected, but may be associated with a lower risk for dental complications [92]. Treatment of mice with XLH

with calcitriol starting prior to the development of enthesitis can prevent enthesopathy [128], but treating Hyp mice with calcitriol and phosphate starting at day 30 (after enthesitis maturation) did not prevent or reduce the extent of enthesopathies [138], suggesting early and consistent therapy is needed to attenuate enthesopathy.

Due to the lack of normalization of the XLH phenotype with conventional therapy, a novel antibody targeting FGF23, burosumab, was developed. The antibody has been studied in adults with XLH, demonstrating that antibody treatment for up to 16 months resulted in significant and sustained increases in serum phosphate and TmP/GFR, while serum 1,25(OH)<sub>2</sub>D levels were transiently increased and normocalcemia was maintained [139,140]. By 48 weeks of therapy, treated adults did not develop hyperparathyroidism, hypercalciuria, or worsening nephrocalcinosis. Adults on burosumab had significant improvement in fracture/pseudofracture healing, skeletal mineralization, and reported pain score, though no decrease in stiffness or improved physical function, as compared with adults treated with placebo [141–143]. In pediatric subjects aged 1 to 12 with severe rickets, burosumab was superior to conventional therapy in improving Rickets Severity Score, serum mineral ion and hormone levels, and growth, although the increase in growth z score was rather modest at 64 weeks [144]. Similar to children with XLH, adults treated with burosumab also demonstrated consistent normalization serum phosphate levels to the low-normal range. Given the efficacy of burosumab in improving serum biochemistries, growth, and skeletal mineralization, it will likely replace conventional therapy as the treatment of choice for XLH. Both treated children and adults continued to develop dental abscesses, and the effects of burosumab on the development of enthesopathies or osteoarthritis have not been reported. Murine studies comparing an alternate FGF23 blocking antibody with daily calcitriol therapy (without phosphate supplementation) in mice with XLH revealed that daily calcitriol was superior to the antibody in improving growth plate morphology, long bone growth, histomorphometric parameters, and skeletal mineralization and biomechanics [89]. Thus, calcitriol alone or in combination with burosumab may potentially be alternative treatment options for XLH patients.

### 3.2.2 Autosomal dominant hypophosphatemic rickets

ADHR is an even rarer disorder characterized by laboratory and clinical findings similar to XLH (Table 64.2). Penetrance is often incomplete, and disease severity can vary considerably. Econs and McEnery described a large kindred, in which affected individuals presented with hypophosphatemia and/or rickets at variable ages,

ranging from early childhood to adolescence to adulthood; the mode of inheritance was autosomal dominant [145,146]. The phenotype at presentation may also vary, where children have short stature and rickets while adults have insufficiency fractures and skeletal pain, but no deformities of the lower extremities. Interestingly, some of the ADHR patients who manifested the phenotype in childhood had normalization of phosphate levels after puberty [145,147], and one patient presented with severe hypophosphatemia and osteomalacia after several uncomplicated pregnancies [148].

To determine the molecular cause of ADHR, Econs et al. used a positional cloning strategy and obtained linkage to a genetic locus on chromosome 12p13.3 in the previously described kindred [146], which subsequently resulted in different kindreds in the identification of heterozygous missense mutations in the *FGF23* gene (R176Q, R179Q, and R179W) [149]. The FGF23 mutations in ADHR patients replace one of two arginine (R) residues within the RXXR motif, a cleavage site for a subtilisin-like proprotein convertase, thus rendering FGF23 resistant to cleavage and increasing the amount of intact biologically active FGF23 in the circulation [48,147,150–152]. Studies where mutant forms of FGF23 carrying known ADHR mutations were expressed in vitro, Western blot analysis predominantly detected the intact form of FGF23, while expression of wild-type FGF23 demonstrated both the intact and cleaved FGF23 species [48]. Similarly, expression of the mutant FGF23 in mice resulted in increased serum levels of biologically active intact FGF23 [153].

The ADHR phenotype is particularly pronounced in individuals with iron deficiency, such as with onset of menses during puberty or during the postpartum period. Serum iron levels are inversely correlated with intact and C-terminal FGF23 levels in patients with ADHR. In unaffected controls, only the C-terminal FGF23 levels show this correlation with iron levels, while intact levels do not [38]. FGF23 expression also increased when mice with ADHR were placed on iron-deficient diet. These animals exhibited reduced renal *Npt2a* and *Cyp27b1* expression with elevations in *Cyp24a1* [37]. Iron supplementation of iron-deficient adults with ADHR normalized serum FGF23 levels and increased serum phosphate levels [154]. These studies demonstrate a role for iron in the maintenance of phosphate homeostasis. They also highlight the importance of the ratio of intact to C-terminal FGF23 in the regulation of phosphate balance.

### 3.2.3 Autosomal recessive hypophosphatemic rickets

The phenotype of autosomal recessive hypophosphatemic rickets (ARHR) resembles that of ADHR and XLH, where patients also show osteomalacia and rachitic skeletal changes early in life, leading to short stature. Like

patients with XLH, affected individuals may also develop dental defects and enthesopathies. The biochemical profile of ARHR is similar to that of ADHR and XLH, with hypophosphatemia, normal or low circulating levels of  $1,25(\text{OH})_2\text{D}$ , increased urinary phosphate excretion, and elevated serum levels of alkaline phosphatase and FGF23 (Table 64.2).

ARHR can be caused by homozygous or compound heterozygous inactivating genetic mutations in the *DMP1* (ARHR type 1), *ENPP1* (ARHR type 2), or *FAM20C* (ARHR type 3) genes. Lorenz-Depiereux et al. mapped the genetic lesion in two families with ARHR to chromosome 4q21, which comprises the *DMP1* gene [155]. Mutations have subsequently been identified that affect either the start codon, alter several other amino acid residues, or introduce splice site mutations [51,155]. Consistent with the human phenotype, the *DMP1*-null mouse exhibit a phenotype consistent with ARHR, including poor skeletal mineralization and rickets combined with low serum phosphate, elevated serum FGF23, and renal phosphate wasting [51]. The intact *DMP1* protein undergoes cleavage into 37- and 57-kDa fragments, where the 57-kDa fragment has been shown to be sufficient to rescue the *DMP1*-null mice from hypophosphatemia and to suppress FGF23 [156].

Loss-of-function mutations of the ecto-nucleotide pyrophosphatase/pyrophosphodiesterase 1 (*ENPP1*) gene have been implicated in ARHR [157]. *ENPP1* regulates skeletal mineralization by hydrolyzing ATP into pyrophosphate ( $\text{PPi}$ ), an inhibitor of mineralization [158]. The *Enpp1*-null mouse is characterized by hypophosphatemia, undetectable pyrophosphate levels, elevated FGF23 serum levels, as well as ectopic calcifications of the aorta, kidney, and spine [159,160]. The identification of *ENPP1* mutations in hypophosphatemic rickets demonstrates that this molecule regulates phosphate homeostasis and FGF23, in addition to its role in modulating skeletal mineralization. Patients with *ENPP1* mutations may present in infancy with generalized arterial calcification of infancy, with variable calcification of medium- and large-vessel arteries that can be life-threatening. These patients can also manifest with early-onset hearing loss, mineralizing enthesopathies, and ossification of the posterior longitudinal ligament of the spine [54,157,161]. During adolescence, serum FGF23 levels begin to rise, leading to hypophosphatemia and rickets; the severity of the rachitic phenotype is variable and correlates with serum FGF23 levels [162,163]. Although limited case reports show that conventional therapy with phosphate and calcitriol supplementation do not worsen arterial calcifications [162], the use of the anti-FGF23 antibody burosumab in an affected patient resulted in increased cardiac and vascular calcifications [164]. More recently, *Enpp1*-null mice treated with

humanized *ENPP1*-Fc prevented organ and cardiovascular calcifications, increased pyrophosphate levels, and improved growth and skeletal microarchitecture, pointing to a potential beneficial role for *ENPP1* enzyme replacement therapy in treating affected patients [165].

Compound heterozygous mutations of *FAM20C*, or the family with sequence similarity 20 member C, have been reported in siblings with hypophosphatemic rickets [166]. *FAM20C* is a kinase located in the endoplasmic reticulum and Golgi network and phosphorylates proteins with the SxE motif, which includes proteins like *DMP1* [167,168] (Fig. 64.3). Therefore, deletion of *FAM20C* may decrease the phosphorylation of *DMP1*, thus inhibiting *DMP1* expression or action and creating a *DMP1*-null phenotype [158]. Studies have also demonstrated that *FAM20C* acts to phosphorylate FGF23 at Ser180, which prevents glycosylation by *GALNT3* and thus renders FGF23 susceptible to cleavage by SPC proteases like furin [47]. Mutations in *FAM20C* increase the ratio of intact to C-terminal FGF23, therefore promoting urinary phosphate excretion. Patients with *FAM20C* mutations can have osteosclerosis, ectopic calcifications in the brain, and significant tooth decay. Interestingly, the phosphate wasting improves over time, and serum levels of phosphate are in the low normal range by the end of puberty [166]. The *Fam20c*-null mouse likewise develops hypophosphatemic rickets, with growth retardation and growth plate expansion [53]. Unlike the human phenotype, the *Fam20c*-null mouse does not have osteosclerosis. Ablation of *FAM20C* in osteogenic cell lines resulted in increased expression of FGF23 and decreased expression of *DMP1* [53].

### 3.2.4 Fibrous dysplasia

In fibrous dysplasia (FD), normal bone is replaced by fibrous tissue. It can affect one bone (monoostotic) or multiple bones (polyostotic) in the craniofacial, appendicular, or axial skeleton [169]. Children with this disorder usually present by 10 years of age with bone pain, fracture, or progressive deformity. FD can manifest on its own or be part of McCune-Albright syndrome, which is caused by somatic postzygotic mutations in *GNAS*, the gene encoding  $G_s\alpha$ , which mediates the actions of numerous G protein-coupled receptors that use the cAMP/PKA signaling pathway; [170] these missense mutations responsible for McCune-Albright syndrome affect only one of two amino acid residues, Arg201 or Gln227 [171]. Affected patients typically have café-au-lait spots and endocrinopathies reflecting abnormal signaling by GPCRs, which can include gonadotropin-independent precocious puberty, thyroid lesions with or without hyperthyroidism, growth hormone excess, hypercortisolism, or testicular lesions with Leydig and/or Sertoli cell hyperplasia [172].

FD patients can have elevated serum FGF23 levels and corresponding low or inappropriately normal serum 1,25(OH)<sub>2</sub>D levels [173]. The degree of urine phosphate wasting and disease burden correlates with FGF23 serum levels [174]. Although fibrous lesions in FD express FGF23, overt hypophosphatemia and classic hypophosphatemic rickets are not frequently observed. It has been shown that there is altered FGF23 cleavage due to decreased glycosylation and increased furin activity in bone marrow stromal cells isolated from FD subjects, thus possibly explaining the lack of a rachitic phenotype in FD [175]. These studies suggest that G<sub>s</sub>α plays a role in the regulation of FGF23 metabolism.

The bone pain that accompanies FD, often more severe in adults than children, can be treated with bisphosphonates. Treatment with bisphosphonates has also been shown to decrease serum FGF23 levels, where the decline in serum FGF23 correlates with an increase in serum 1,25(OH)<sub>2</sub>D levels [173]. However, there may be an increased risk of osteonecrosis of the jaw in FD patients on bisphosphonate therapy [176]. There is limited data on the efficacy of denosumab (anti-RANKL antibody) in therapy for FD. Administration of denosumab to fibrous dysplasia patients can decrease bone turnover markers, bone pain, and expansion of bony lesions. Thus, its use should be closely monitored in patients, as treatment with denosumab has been reported to cause worsening hypophosphatemia and secondary hyperparathyroidism [177]. Discontinuation of denosumab treatment can be complicated by rebound osteoclast activation, leading to hypercalcemia [178]. However, a pediatric patient with McCune-Albright syndrome/FD with frank hypophosphatemia and rickets, who was treated with burosumab, revealed improvement in mineral ion homeostasis, decreased fractures, and improved bone pain and strength [179].

### 3.2.5 Linear nevus sebaceous syndrome/epidermal nevus syndrome

Linear nevus sebaceous syndrome (LNSS), also known as epidermal nevus syndrome (ENS), is a rare, sporadic, and highly variable disorder that is characterized by papillomatous epidermal hyperplasia as well as abnormalities in multiple organ systems, including neurologic, ophthalmic, cardiovascular, and urogenital deformities [180]. LNSS/ENS is also associated with hypophosphatemic rickets due to elevated serum FGF23 levels, although the source of the FGF23 had not yet been elucidated [181,182]. Affected individuals can present with overtly low serum levels of 1,25(OH)<sub>2</sub>D [181]. In recent studies, whole-exome sequencing identified somatic postzygotic activating mutations of the *HRAS* or *NRAS* genes in affected skin and bone tissue from ENS patients with elevated serum FGF23 levels, suggesting that RAS signaling may be

important for the modulation of FGF23 [182]. Since the skin lesions have not been found to express FGF23 mRNA or protein, it is postulated that dysplastic bone lesions could be the source of the excess circulating FGF23.

## 3.3 Genetic hypophosphatemic disorders with low FGF23 levels

### 3.3.1 NPT2a mutations

The type II sodium phosphate cotransporter (NPT2a, *SLC23A1*) is expressed exclusively in the brush border membrane of renal proximal tubular cells. Ablation of *Npt2a* in mice leads to increased renal phosphate excretion, resulting in hypophosphatemia and a compensatory decrease in serum FGF23, as well as an increase in serum 1,25(OH)<sub>2</sub>D levels, which increases intestinal calcium absorption and thus hypercalcemia, hypercalciuria, and leads to low PTH levels [183,184]. The age-dependent increase in serum 1,25(OH)<sub>2</sub>D levels corresponded with the resolution of rickets in these mice [183].

Two heterozygous mutations in the *SLC34A1* gene (A48P and V147M) were identified in patients, who presented with idiopathic hypophosphatemia, recurrent urolithiasis, and skeletal demineralization [185]. Co-expression studies in *Xenopus laevis* oocytes revealed that the mutant NPT2a resulted in a dominant negative effect of the mutant proteins [185]. Heterozygous mutations in the *SLC34A1* gene (91del7, A133V, H568Y) have also been reported in a cohort of patients with recurrent kidney stones [186]. Despite the nephrolithiasis, these patients did not manifest hypercalciuria, hypophosphatemia, or increased urinary phosphate excretion [186]. A cohort of children diagnosed with idiopathic infantile hypercalcemia was found to have autosomal recessive mutations in *SLC34A1* [88]. Most of these infants presented with severe hypercalcemia, profound renal phosphate wasting, and suppressed serum PTH. Approximately half of these patients had elevated serum 1,25(OH)<sub>2</sub>D levels during hypercalcemia. Metabolic abnormalities resolved with phosphate supplementation [88], which is thought to lower 1,25(OH)<sub>2</sub>D levels, to prevent absorptive hypercalciuria in affected patients, and to thereby prevent nephrocalcinosis. However, mice lacking *Npt2a* fed high-phosphate diets with or without high calcium were more likely to develop renal calcifications compared to wild-type mice fed a similar diet, suggesting optimization of dietary content of phosphate and calcium is needed in treating affected individuals [187].

### 3.3.2 NPT2c mutations

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is a rare autosomal recessive that was first

described in a large consanguineous Bedouin kindred in the mid-1980s [188,189]. Biochemical features in the affected family members are similar to those in mice with homozygous ablation of *Npt2a*, namely affected patients have low serum phosphate and increased urinary phosphate excretion, leading to decreased FGF23 levels, rickets/osteomalacia, and short stature. The appropriate elevation of serum 1,25(OH)<sub>2</sub>D levels in these patients increases intestinal calcium absorption and suppresses serum PTH levels, thus resulting in hypercalciuria [188,189] (Table 64.2). Linkage studies using this and other smaller families lead to the identification of the genetic locus of this disease, and the subsequent identification homozygous and compound heterozygous mutations in the gene encoding NPT2c (*SLC34A3*) [190,191]. Reported human mutations in *SLC34A3* characterized using in vitro expression systems demonstrated that these mutations compromised the activity, expression, or stability of NPT2c [192].

Furthermore, these and other HHRH kindreds with documented *SLC34A3* mutations exhibit a significant increase in the occurrence of kidney stones. Thus, 46% of subjects with *SLC34A3* mutations on both alleles manifested nephrocalcinosis compared with 6% of non-affected family members [193]. Even heterozygous carriers of *SLC34A3* mutations have a higher frequency of renal calcifications that is intermediate to that seen in subjects with homozygous/compound heterozygous mutations and subjects without such mutations. The likelihood of renal calcifications increased with the severity of hypophosphatemia and decreased tubular reabsorption of phosphate [193]. The identification of *SLC34A3* mutations in HHRH has documented that NPT2c plays an important role in the regulation of phosphate homeostasis [194].

### 3.4 Acquired hypophosphatemic disorders with elevated FGF23 levels

#### 3.4.1 Tumor-induced osteomalacia

Tumor-induced osteomalacia (TIO), also known as oncogenic osteomalacia, is a rare paraneoplastic disorder that manifests with often profound urinary phosphate excretion and thus hypophosphatemia, low or inappropriately normal circulating levels of 1,25(OH)<sub>2</sub>D [195] (Table 64.2). In most cases, the cause of these mineral ion and hormonal abnormalities has been attributed to tumors secreting FGF23 [35,196] and consequently elevated levels of FGF23 in the circulation [46,197]. In patients whose FGF23 levels are not elevated, increased circulating levels of other phosphatonins such as secreted frizzled related protein-4 (SFRP4), matrix extracellular phosphoglycoprotein (MEPE), or fibroblast growth factor 7 (FGF7), have

been reported to cause TIO [198–200]. However, while the infusion of SFRP4 into rats results in increased phosphaturia and hypophosphatemia without changes in serum levels of 1,25(OH)<sub>2</sub>D or renal expression of 25-hydroxyvitamin D 1 $\alpha$ -hydroxylase [199], mice with ablation of *Sfrp4* revealed no abnormalities in mineral ion homeostasis [201]. More recently, phosphaturic tumors expressing fusion products FN1-FGF1 or FN1-FGFR1 have been identified, supporting an important role of FGFR1 signaling in phosphate homeostasis [39].

TIO patients have osteomalacia and increased incidence of fractures. Children may manifest with gait disturbances and growth retardation. Tumors found in patients with TIO are predominantly of mesenchymal in origin and can be very slow growing and difficult to localize, often presenting in obscure or inaccessible areas such as the nasopharynx or mandible. Functional imaging is important for detection and localization of tumors. Since somatostatin receptors are often highly expressed on phosphaturic tumors, imaging modalities using radioisotopes to target these receptors are effective in localizing tumors. The <sup>68</sup>Ga-DOTATE PET/CT has the highest sensitivity and specificity for detecting tumors [202,203]. Also, <sup>18</sup>FDG-PET/CT can aid in detection of lesions of high metabolic activity. The duration of symptoms prior to diagnosis can range from a few months to 19 years [204]. Cure for this disorder is surgical resection. However, if the tumor cannot be found or completely resected, therapy with calcitriol and phosphate supplementation can help improve the metabolic and bone abnormalities [204]. In cases of incurable TIO due to FGF23 secreting tumors, the humanized anti-FGF23 antibody burosumab has been used to increase serum phosphate levels and improve osteomalacia [205].

### 3.5 Genetic hyperphosphatemic disorders

#### 3.5.1 Tumoral calcinosis

Tumoral calcinosis is a rare disorder characterized by hyperphosphatemia, leading to deposition of calcium phosphate crystals in soft tissue, bone, and periarthral spaces. Cases of tumoral calcinosis in North America have largely been reported in African Americans. However, case reports have also been published identifying this disorder in patients from Turkey, Iran, Kenya, and Saudi Arabia [206–209]. Tumoral calcinosis is predominantly sporadic but can be autosomal recessive. In addition to elevated serum phosphate levels, biochemical consequences of tumoral calcinosis include increased urinary TmP/GFR and inappropriately normal or increased serum 1,25(OH)<sub>2</sub>D levels (Table 64.2). Serum calcium and

PTH levels are usually normal. The elevated calcium phosphate product results in the deposition of calcific tumors. Patients can present with a wide range of involvement, from no calcified lesions to large and painful masses [210]. There is a predilection for these calcified lesions to occur in the hips, elbows, shoulders, and scapulae [211]. There have also been reports of lesions in the vasculature and eye as well as dental abnormalities with short roots and pulp stones [211]. Patients can also present with hyperostosis or systemic inflammation, manifesting with fevers or polyarthritis, along with high serum C-reactive protein levels, thought to be due to an inflammatory response from macrophages trying to engulf calcific lesions [210].

Outcomes of treatment for tumoral calcinosis can be variable. It has been suggested that the fibrous encapsulation of the calcified tumors can make phosphate deprivation therapy ineffective for decreasing the size of the lesions [211]. Calcific masses may be surgically excised when appropriate, though regrowth of lesions may occur because they may be poorly circumscribed [211]. However, phosphate deprivation with a diet low in calcium and phosphorus combined with aluminum hydroxide containing antacids has resulted in biochemical, clinical, and radiographic improvement in case reports of patients with tumoral calcinosis [212,213]. Furthermore, administration of the non-calcium phosphate binder sevelamer in combination with acetazolamide can also reduce serum phosphate levels and decrease the size of calcified lesions [214,215]. It is recommended that phosphate binders should be given prior to each meal and that dietary phosphate be restricted to 600–800 mg/day. Preclinical studies demonstrated that treatment of mice or rats with chronic renal disease and hyperphosphatemia or mice with tumoral calcinosis (Galnt3- or Fgf23-null mice) with a novel NPT2a small molecule inhibitor decreases serum phosphate levels and increases phosphaturia, suggesting that this inhibitor has the potential to be used as a treatment for tumoral calcinosis [216,217].

The genetic defects underlying tumoral calcinosis include mutations in the genes encoding FGF23, GALNT3, or *Klotho*, all of which lead to a defect in FGF23 action, and thus hyperphosphatemia and elevated 1,25(OH)<sub>2</sub>D levels. The biochemical phenotype for this disorder is therefore a mirror image of hypophosphatemic rickets, where there is an excess of FGF23 action. Biallelic inactivating FGF23 mutations have been reported. Full-length FGF23 is either destabilized or not secreted due to retention in the Golgi apparatus [218,219]. In these cases, affected individuals had increased circulating levels of the biologically inactive C-terminal FGF23 fragments and decreased circulating levels of intact FGF23 [218,219].

UDP-N-acetyl- $\alpha$ -D-galactosamine:polypeptide N-acetylgalactosaminyl-transferase 3 (GALNT3) is responsible for the mucin-type O-glycosylation of FGF23 at a subtilisin-like pro-protein convertase recognition sequence motif, which is essential for the secretion of biologically active intact FGF23 [220]. Homozygous or compound heterozygous *GALNT3* mutations have been reported in patients with defects in the posttranslational modification of FGF23 resulting in tumoral calcinosis [221,222]. Circulating levels of intact FGF23 are normal or low, while C-terminal fragments of FGF23 are elevated [221,223]. Compound heterozygous *GALNT3* mutations have also been reported in patients who presented with hyperostosis of the tibia combined with hyperphosphatemia and elevated 1,25(OH)<sub>2</sub>D levels, suggesting hyperostosis–hyperphosphatemia syndrome may be a continuum of the tumoral calcinosis phenotype. Like other cases of tumoral calcinosis, this patient also had elevated circulating levels of C-terminal FGF23 fragments and low levels of intact FGF23 [224].

Homozygous mutations in the *Klotho* gene have been reported in a patient who presented with severe vascular and soft tissue calcifications, as well as increased serum levels of calcium, PTH and 1,25(OH)<sub>2</sub>D [225]. The phenotype is consistent with that of the *Klotho*-null mouse, which is also characterized by ectopic soft tissue and vascular calcifications. Both mice and humans with homozygous *Klotho* mutations have elevated circulating FGF23 levels. Analysis of the His193Arg change demonstrated that this *Klotho* mutation caused destabilization of the *Klotho* protein, thereby decreasing its production and secretion [225]. Consequently, in the absence of *Klotho*, FGF23 was unable to bind to the FGFR1 demonstrating the importance of this co-receptor in FGF23-mediated phosphate and 1,25(OH)<sub>2</sub>D homeostasis.

## 3.6 Disorders of altered phosphate load

### 3.6.1 Phosphate deprivation

Although low serum phosphate due to poor dietary intake is rare, severe hypophosphatemia has been reported in children with kwashiorkor or marasmic kwashiorkor [226]. Up to 86% of children admitted for kwashiorkor in the Kenyatta National Hospital in Nairobi had hypophosphatemia. Following nutritional intervention, serum phosphate levels decreased further during the first 2 days of treatment [226], suggesting a refeeding syndrome. Serum phosphate levels of less than 1.0 mg/dL were described in a cohort of children presenting with kwashiorkor in Malawi, where the severity of hypophosphatemia correlated with the fatality rate [227].

In rats gavaged with a low phosphate diet, serum phosphate levels declined by 1 h post-gavage,

associated with increased renal tubular phosphate reabsorption. Thyroparathyroidectomized rats demonstrated similar rates of renal phosphate uptake during phosphate deprivation, suggesting that the renal adaptation to hypophosphatemia is independent of PTH [228]. Similarly, healthy male subjects placed on a low phosphate diet with aluminum hydroxide exhibited increased TmP/GFR, unchanged serum PTH levels, as well as compensatory increased serum 1,25(OH)<sub>2</sub>D levels [60]. In another study, administration of a low phosphate diet to healthy males and females suppressed urinary phosphate excretion and decreased serum PTH levels [16].

### 3.6.2 Gastrointestinal malabsorption

Hypophosphatemia may result from chronic ingestion of high doses of phosphate binder medications including calcium acetate or sevelamer [229]. Generally, mild or moderate doses of phosphate binders do not result in phosphate depletion. Use of medications such as aluminum or magnesium containing antacids has also been reported to cause low serum phosphate levels, leading to osteomalacia and myopathy [230,231]. The combination of hypophosphatemia with increased 1,25(OH)<sub>2</sub>D levels impaired skeletal mineralization. Healthy subjects who ingested a combination of low phosphate diet and antacids for 3 months had serum phosphate levels at as low as 1 mg/dL [230].

Disorders where there is a decreased vitamin D adsorptive capacity in the gut can also lead to lower serum phosphate levels. In small bowel resection and Crohn's disease, there is reduced surface area for vitamin D adsorption [232,233]. Also, vitamin D deficiency can result from steatorrhea in cystic fibrosis or chronic pancreatitis [234]. Vitamin D deficiency can lead to secondary hyperparathyroidism, where both processes contribute to the mild to moderate hypophosphatemia observed in malabsorptive disorders. In response to the elevation in PTH levels, serum levels of 1,25(OH)<sub>2</sub>D can also increase. Patients who underwent bariatric surgery have higher serum 1,25(OH)<sub>2</sub>D levels by 3–6 months post-procedure, where levels are significantly increased by 12 months. Circulating 1,25(OH)<sub>2</sub>D levels are higher in patients receiving Roux-en-Y gastric bypass or biliopancreatic diversion with duodenal switch as compared with gastric banding [235].

## 4. Conclusion

Characterization of molecular basis of genetic and acquired disorders of phosphate homeostasis has resulted in a greater understanding of the molecular regulation of phosphate balance. Phosphate is modulated by an

interplay of mineral hormones, where the manifestations of disruptions of these hormones have allowed for better insights into the molecular and skeletal processes that these hormones regulate. While significant advances have been made in deciphering the genetic and molecular basis for disorders of phosphate homeostasis, major gaps still exist in the availability of appropriate treatments of the complications of these disorders.

## 5. Summary points

- The proximal tubule of the kidney is the major site of phosphate reabsorption.
- Phosphate homeostasis is regulated by FGF23, 1,25(OH)<sub>2</sub>D, and PTH.
- Phosphate disorders with high serum FGF23 levels are characterized by hypophosphatemia and inappropriately normal serum 1,25(OH)<sub>2</sub>D levels, leading to rickets and osteomalacia. They include genetically inherited diseases such as XLH and acquired disorders such as TIO.
- Phosphate disorders that have low serum FGF23 levels are caused by mutations in renal sodium phosphate transporters that lead to increased phosphaturia and thus hypophosphatemia.
- Hyperphosphatemic disorders such as tumoral calcinosis result in formation of debilitating ectopic calcium phosphate deposits in soft tissue.
- Poor dietary intake of phosphate or gastrointestinal malabsorption of phosphate can lead to hypophosphatemia.

# The hypocalcemic disorders

Nadia Merchant<sup>1</sup> and Rachel I. Gafni<sup>2</sup>

<sup>1</sup>Children's National Hospital, Washington, DC, United States <sup>2</sup>National Institute of Health, Bethesda, MD, United States

## OBJECTIVES

- Review calcium physiology and regulation by vitamin D and parathyroid hormone.
- Describe the clinical manifestation of hypocalcemia.
- Present the differential diagnosis of hypocalcemia: abnormalities in parathyroid hormone availability, resistance to actions of parathyroid hormone and parathyroid hormone-independent hypocalcemia.
- Discuss treatment of hypocalcemia.

## 1. Introduction

Calcium is maintained within a narrow range by calcitropic hormones, including parathyroid hormone (PTH), and vitamin D. Hypocalcemic disorders are classified by their functional etiologies and discussed in relationship to primary homeostatic disturbances including inadequate PTH secretion, resistance to PTH action, or PTH independence. Identifying the underlying etiology of hypocalcemia is important, as therapeutic options and treatment goals vary depending on the specific cause.

## 2. Physiology of hypocalcemia

Hypocalcemia refers to an abnormally low concentration of circulating ionized calcium. Regulatory mechanisms maintain the concentration of ionized calcium

within a remarkably narrow range of 4.48–5.28 mg/dL (1.12–1.32 mmol/L) in whole blood [1]. The ionized fraction of total serum calcium is estimated to be ~ 50%, with the remainder of the total serum calcium bound to serum proteins, most notably albumin, and to a lesser extent complexed with anions, such as citrate or sulfate. Only the ionized fraction of total serum calcium is physiologically important, and it is this component that is regulated on a minute-to-minute basis.

Although it is possible to measure ionized calcium in large clinical laboratories, the specimen must be obtained anaerobically and analyzed promptly. Therefore, total serum calcium is often used as an indirect assessment of the ionized calcium fraction. A decrease in serum protein concentrations (particularly albumin) often results in reduced total serum calcium concentrations but does not affect the ionized calcium concentration. Such patients are asymptomatic, displaying none of the signs or symptoms of hypocalcemia. These findings are often present in patients with nephrotic syndrome, chronic illness, malnutrition, cirrhosis, and volume overexpansion. Occasionally, ionized calcium levels may transiently fall when protein losses are substantial (e.g., in severe nephrotic syndrome and protein-losing enteropathies), presumably due to massive losses of both ionized and protein-bound calcium. Several clinical guidelines have been suggested, which correct the effect of a reduced serum albumin on total serum calcium concentration. One commonly cited rule of thumb is to add 0.8 mg/dL to the total serum calcium for every 1 g/dL decline in serum albumin below 4.0 g/dL. However, these estimates are somewhat inaccurate under many circumstances, and it may be preferable to directly determine the ionized calcium concentration in the setting where the total serum calcium measure is thought to not accurately

reflect the concentration of ionized calcium [2]. Additionally, acidosis decreases the binding of calcium to protein, and alkalosis increases protein binding. As such, alkalosis leads to a decrease in ionized calcium concentration as the protein-bound fraction increases [3], which may precipitate hypocalcemic symptoms.

## 2.1 Parathyroid hormone in the acute defense of serum calcium concentration

PTH is secreted by the parathyroid glands in response to a fall in ionized serum calcium concentration [1]. The relationship between decrements in ionized calcium within the physiological range and increments in PTH secretion is quite steep, permitting rapid and substantial changes in PTH secretion in response to minor fluctuations in ionized calcium [1]. This response is mediated by the seven-transmembrane-domain, G protein-coupled calcium-sensing receptor (CaSR), which is expressed in the parathyroid glands and in a variety of other tissues. A rise in ionized calcium suppresses PTH secretion by activating this receptor [1].

PTH acts to regulate ionized calcium through its effects in three principal target tissues: the bone, kidney, and, indirectly, the intestine. The cellular actions of PTH are mediated by the PTH receptor, also a seven-transmembrane-domain, G protein-coupled receptor [4]. Downstream signaling from the PTH receptor involves activation of both protein kinase A (PKA)-dependent and protein kinase C (PKC)-dependent pathways [5,6]. In bone, PTH indirectly increases bone resorption, by stimulating osteoblastic and osteocytic expression of the receptor activator of nuclear factor kappa-B (RANK) ligand and inhibiting expression of the decoy receptor osteoprotegerin (OPG), thus increasing the RANK ligand/OPG ratio. When RANK ligand binds to its receptor RANK, expressed on the surface of osteoclast progenitors, osteoclastogenesis is promoted, leading to increased bone resorption and liberation of calcium from the mineralized matrix into the circulation [7–9].

The renal effects of PTH to defend serum calcium occur within minutes. PTH increases calcium reabsorption in the distal tubule. This effect is greatest in the distal convoluted tubule, where a sodium/calcium exchanger is regulated by PTH [10]. The transient receptor potential vanilloid 5 (TRPV5) calcium channel, another mediator of calcium reabsorption in the distal tubule, is also regulated by PTH. PTH increases the calcium inward flux of TRPV5, a PKA-mediated function [11], decreases endocytosis of TRPV5, a PKC-mediated function [12], and increases expression of TRPV5 [13]. Channel function of TRPV5 is also enhanced by the protein KLOTHO, which serves to preserve its integration in the membrane due to exposure of glycosaminoglycan-binding sites [14]. In the

proximal renal tubule, PTH acts via a cyclic adenosine monophosphate (cAMP)-dependent mechanism to decrease phosphate reabsorption, resulting in phosphaturia. PTH effects this change by prompting the removal of sodium/phosphate cotransporters from the renal tubular apical membrane [15]. These two effects both serve to acutely increase serum calcium; the combination of reduced renal calcium excretion combined with decreased serum phosphate levels favors an increase in ionized calcium.

The third site of action of PTH in the defense of serum calcium is the intestine. This is an indirect effect, described in detail in the following, and is a consequence of the ability of PTH to stimulate the renal production of 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ).

## 2.2 Vitamin D in the long-term maintenance of eucalcemia

Long-term eucalcemia is maintained, in large part, via the vitamin D endocrine system. This system operates in the classic manner of a steroid hormone, resulting in *de novo* protein synthesis directed by vitamin-D-responsive genes as discussed in detail in other sections. As noted before, acute changes in serum ionized calcium levels are sensed by G protein-coupled CaSRs located within the parathyroid cell membrane. PTH acts rapidly to correct a fall in serum calcium, and a sustained increase in PTH also stimulates production of  $1,25(\text{OH})_2\text{D}$ , which enhances intestinal calcium absorption. PTH mediates this change by promoting the increased expression of *CYP27B1*, which encodes the catalytic component of the renal 25-hydroxyvitamin D ( $25(\text{OH})\text{D}$ ) 1- $\alpha$ -hydroxylase ( $1\alpha\text{-OHase}$ ) enzyme complex, located in the inner mitochondrial membrane of renal tubular cells (see Chapter 8). A number of physiological studies have demonstrated increased production of  $1,25(\text{OH})_2\text{D}$  in animals that were administered PTH [16,17] and decreased production following parathyroidectomy [18]. PTH also acutely regulates the  $1\alpha\text{-OHase}$  enzyme complex by altering the phosphorylation state of the associated ferredoxin molecule, which serves to donate electrons to the catalytic complex [19]. A low extracellular calcium concentration can directly stimulate  $1\alpha\text{-OHase}$  activity in the absence of PTH as described in para-thyroidectomized rats [20] and in hypo-parathyroid humans [21].

Dietary calcium is absorbed mainly in the small intestine. When the intraluminal concentration of calcium is high, calcium absorption occurs primarily via a passive non-saturable paracellular pathway [22]. In states of decreased circulating calcium with a compensatory rise in PTH, increased synthesis of  $1,25(\text{OH})_2\text{D}$  results in greater circulating levels of the metabolite, which gain access to specific vitamin D receptors (VDRs). The

hormone–receptor complex then binds to vitamin D response elements in the regulatory regions of target genes to promote active absorption of calcium via transcellular pathways (see Chapters 10–13). Long-term control of calcium homeostasis has been thought to be classically mediated by  $1,25(\text{OH})_2\text{D}$  induction of the calcium channel TRPV6 [23] and the intestinal 9 kDa calcium-binding protein, calbindin-D9k, which is thought to play a role in vitamin D–mediated increases in calcium absorption in the jejunum and duodenum [24,25]. These proteins, however, may not be necessary for calcium absorption because mice in which both these proteins have been deleted still demonstrate substantial active intestinal calcium transport [26,27]. Rapid, non-genomic actions of  $1,25(\text{OH})_2\text{D}$ -mediating calcium transport across intestinal mucosa have also been described [28].

During vitamin D deprivation, the initial decline in ionized calcium results in secondary hyperparathyroidism, which maximizes  $1,25(\text{OH})_2\text{D}$  production and initially allows for maintenance of eucalcemia. Eventually, this compensatory mechanism fails, and intestinal calcium absorption is sufficiently compromised such that frank hypocalcemia develops. This may be compounded by an induced resistance to PTH seen in severe vitamin D–deficient states [29,30].

In children with hereditary resistance to vitamin D due to loss-of-function variants in the vitamin D receptor, the compensatory changes described before are disrupted because of nonfunctional VDRs that result in the inability of  $1,25(\text{OH})_2\text{D}$  to signal to the nucleus [31]. Untreated patients with VDR variants can have severe hypocalcemia, leading to convulsions, coma, and death, as this homeostatic system is effectively absent (see Chapter 68).

The vitamin D system has further complexities that are currently not well understood. For example, some children with vitamin D deficiency (defined by low  $25(\text{OH})\text{D}$  levels) manifest hypocalcemia even when circulating  $1,25(\text{OH})_2\text{D}$  levels are elevated. Possible explanations for this phenomenon include decrements in expression of calbindin during hypocalcemia or a requirement for other circulating vitamin D metabolites, which have yet to be identified. Whether changes in the concentration of VDR levels play a role in this “resistant” state is not clear, as receptor levels have been reported to increase, decrease, or not change with manipulation of the ambient calcium concentration [32–34] (see Chapters 62–64).

### 2.3 Biochemical changes induced by hypocalcemia

As noted before, the most rapid response to hypocalcemia is secretion of PTH. In addition to increasing

serum calcium levels, PTH stimulates renal phosphate (Pi) excretion. The fall in serum phosphate may, however, be compensated by sufficient mobilization of phosphate (as well as calcium) from bone, so that circulating phosphate remains largely unchanged. The principle of mass action is thought to maintain the stability of the  $\text{Ca} \times \text{Pi}$  ion product in the blood. Therefore, local concentrations of the two major mineral components of hydroxyapatite (Ca and Pi) can influence the rate of movement in and out of the mineral phase of bone.

Thus, a fall in ionized Ca would favor an increase in serum phosphate concentration. In aggregate, however, sustained hypocalcemia usually results in a biochemical picture of secondary hyperparathyroidism, elevated  $1,25(\text{OH})_2\text{D}$  levels, and variable changes in serum phosphate. If hypocalcemia develops in the setting of diminished or absent PTH function, serum phosphate is usually elevated, owing to decreased renal phosphate excretion. In this instance, treatment with  $1,25(\text{OH})_2\text{D}$  would also increase serum phosphate because this metabolite enhances intestinal phosphate absorption. The effect of hypocalcemia on circulating vitamin D metabolites is complex. An increase in the biosynthesis of  $1,25(\text{OH})_2\text{D}$  occurs, as reviewed before. This is largely secondary to the induced increase in circulating PTH but can be a direct consequence of the fall in calcium ion concentration. It has been determined that calcium deprivation results in a general increase in turnover of the parent vitamin D metabolite,  $25(\text{OH})\text{D}$ , such that vitamin D stores are depleted at a more rapid rate than normal [35]. The clinical implication of this finding is that susceptibility to vitamin D deficiency may be greater in the setting of concomitant calcium deprivation (see Fig.65.1).

### 3. Clinical manifestations of hypocalcemia

Manifestations of hypocalcemia are related to increased neuromuscular irritability [36]. Tetany is the classic sign of hypocalcemia, yet it is variable in presentation. Paresthesia often occurs first around the mouth or in the fingertips and may progress to overt spasm of the muscles of the face and extremities, the latter typified by carpopedal spasm. More subtle presentations have included complaints of writer’s cramp or generalized stiffness. Children with tetanic laryngospasm due to hypocalcemia have been mistakenly diagnosed with croup [37]. Infants are more likely than adults to present with jitteriness or twitching, which can progress to overt tonic–clonic seizures. Lethargy and cyanosis have also been described in this age group. The term latent tetany refers to signs elicitable with provocative stimuli such as ischemia (Trousseau test) or percussion (e.g., of the facial

**FIGURE 65.1** Mechanisms of the development of osteomalacia and rickets. Deficiency of vitamin D intake and/or limited ultraviolet light exposure lead to limited vitamin D stores as reflected by a decreased circulating 25(OH)D level. Reduced availability of this substrate is presumed to limit 1,25(OH)<sub>2</sub>D production, resulting in impaired intestinal calcium absorption. Calcium availability for skeletal mineralization is subsequently compromised, and secondary hyperparathyroidism, with concomitant hypophosphatemia, occurs. Restricted dietary calcium intake can also result in a similar pathophysiology. Increased turnover of vitamin D in the calcium-deficient state may result in a greater risk of vitamin D insufficiency. The paradox of elevated levels of 1,25(OH)<sub>2</sub>D in these disorders is well recognized. PTH, parathyroid hormone.

nerve to elicit Chvostek's sign). Neither the degree of hypocalcemia nor the rapidity with which it develops necessarily correlates with clinical manifestations. Many individuals with chronic, mild hypocalcemia may be entirely asymptomatic, as can be seen in congenital hypoparathyroidism.

Hypomagnesemia or hyperkalemia may present with findings like those caused by hypocalcemia, which can be exacerbated in the setting of hypocalcemia. Conversely, hypermagnesemia or hypokalemia can mask symptoms in a hypocalcemic individual [38]. Abnormalities of cardiac repolarization can occur with hypocalcemia resulting in a prolonged QT interval on the electrocardiogram (EKG). The QT interval corrected for heart rate (QTC, which equals QT/(RR interval)<sup>1/2</sup>) is normally less than  $0.40 \pm 0.04$  s. This abnormality is not always present during hypocalcemia, and it may also be seen in hypokalemia. Cardiac failure may rarely occur in the setting of hypocalcemia [39]. Papilledema has also been reported [40].

Chronic hypocalcemia caused by calcium deficiency, due to inadequate intake/intestinal absorption or excessive renal losses, during skeletal growth may result in rickets, osteomalacia, and osteoporosis. While dental abnormalities have also been reported in long-standing untreated hypoparathyroidism [41], osteoporosis is uncommon in hypoparathyroidism. To the contrary, adults with hypoparathyroidism typically display increased bone density, associated with a low bone turnover state

[42]. Despite marked hypocalcemia, rickets is not seen in hypoparathyroidism, due to the absence of hypophosphatemia. Basal ganglia calcifications and cataracts, associated with a decreased calcium:phosphate ratio, are typical findings in long-standing hypoparathyroidism as well [43–45]. Abnormalities in the integument including dry skin, coarse hair, and a form of psoriasis that responds to normalization of the serum calcium concentration [46] have all been described in states of long-standing hypocalcemia.

## 4. Differential diagnosis of hypocalcemia

### 4.1 Classification

A rapid increase in PTH serves as the major defense against acute hypocalcemia. Thus, hypocalcemic disorders can be divided into disorders of decreased PTH availability, impaired PTH signaling, or PTH-independent hypocalcemia. While many of the etiologies of hypocalcemia are directly related to abnormalities in PTH, vitamin D metabolism is always involved, and vitamin D is often the cornerstone of therapy.

### 4.2 Hypocalcemia due to abnormalities of parathyroid hormone availability

A variety of congenital or acquired disorders can lead to developmental failure of the parathyroid glands, failure of functional hormone production, or destruction of the parathyroid glands (Table 65.1). These are all associated with variable degrees of hypocalcemia, usually with attendant hyperphosphatemia and undetectable or inappropriately low levels of circulating PTH.

### 4.3 Disorders of parathyroid gland formation

The condition 22q11.2 deletion syndrome (22q11.2DS) is the most frequent chromosomal microdeletion syndrome, with an estimated frequency of about 1/4000 in children under a year of age. One of the cardinal features is dysgenesis of the thymus and the parathyroid glands. The syndrome has been assigned several names in the past, including DiGeorge syndrome, velocardiofacial syndrome, and conotruncal anomaly face syndrome. The syndrome has a broad phenotype ranging from mild intellectual disabilities, congenital heart disease, parathyroid abnormalities, significant neurocognitive impairments, and risk for psychiatric disorders [47]. Tetany and seizures are common features of the early course of infants with 22q11.2DS with hypocalcemia reported as a feature in up to 60% of cases. Abnormalities in T cell function with subsequent increased risk for infection are also a

Familial isolated hypoparathyroidism type 1 (FIH)	AR or AD	11p15.3	PTH	146200	
Autosomal dominant hypocalcemia type 1 (ADH1)	AD	3q13.3–21	CASR	601198	Variable degree of severity, hypomagnesemia, hypercalciuria; some variants associated with Bartter syndrome type V Hypomagnesemia, hypercalciuria
Autosomal dominant hypocalcemia type 2 (ADH2)		19p13.3	GNA11	615361	
<i>Parathyroid gland damage/destruction</i>					
Complication of neck surgery					May be transient
Infiltrative disease/heavy metals					Hemochromatosis, Wilson disease, metastases
Autoimmune hypoparathyroidism		Polygenic			Maybe associated with other autoimmune diseases
Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome (APECED)	AD, AR	21q22.3	AIRE	240300	Adrenal insufficiency, mucocutaneous candidiasis, malabsorption, vitiligo, alopecia, hepatitis, pernicious anemia, hypogonadism, asplenia

**TABLE 65.1** Hypocalcemia due to abnormalities of parathyroid hormone.—cont'd

	Inheritance	Locus	Gene	OMIM	Associated abnormalities
<i>Resistance to PTH</i>					
Hypomagnesemia					As noted above
Severe vitamin D deficiency Vitamin D–dependent rickets, type 3	AD	7q22.1	<i>CPY3A4</i>	619073	Corrects with vitamin D replacement, many consider this to be the cause of pseudohypoparathyroidism type II Early-onset rickets, reduced serum levels of vitamin D metabolites, and no responsiveness to all forms of vitamin D
Pseudohypoparathyroidism Ia (PHP1a)	AD	20q13.32 (maternal)	<i>GNAS</i>	103580	Albright's hereditary osteodystrophy (AHO), obesity, other hormone resistance
Pseudopseudohypoparathyroidism (PPHP)	AD	20q13.32 (paternal)	<i>GNAS</i>	612463	AHO without obesity or hormone resistance
Pseudohyparathyroidism Ib (PHP1b)	Sporadic or AD	20q13.32 (maternal)	<i>GNAS</i> <i>STX16</i>	603233	Due to imprinting defects upstream of <i>G<sub>s</sub>α</i> promoter, nondysmorphic, may have TSH resistance
Pseudohypoparathyroidism Ic (PHP1c)	AD	20q13.32 (maternal)	<i>GNAS</i>	612462	Identical phenotype to PHP1a, normal <i>G<sub>s</sub>α</i> activity in erythrocytes, receptor coupling possibly affected

major feature of this disorder [48]. Deletions, translocations, and rearrangements of the chromosome 22q11.2 region occur in this disorder, with *TBX1*, a member of the t-box family of transcription factors, identified as the gene responsible for its characteristic craniofacial, parathyroid, and cardiac anomalies [49,50]. It is believed that contiguous genes, as well as a variety of other genetic modifiers, are responsible for the broad spectrum of findings that exist in patients with 22q11.2 deletion syndrome. Deletions at a second locus on chromosome 10p have been identified as the cause for a phenotypically similar condition, termed DiGeorge syndrome II [51].

Several other genes have been identified as critical to parathyroid development. Loss-of-function variants have been identified as the genetic basis for some human hypoparathyroid syndromes [52]. These include loss-of-function variants in the parathyroid-specific transcription factor, glial cells missing B (*GCMB*), usually manifesting as familial, isolated hypoparathyroidism [53]. The combination of familial hypoparathyroidism, sensorineural deafness, and renal dysplasia (Barakat syndrome) is an autosomal dominant disorder due to pathogenic variants in the *GATA3* transcription factor [54,55]. An autosomal recessive condition of hypoparathyroidism, mental retardation, dwarfism, tubular deformities of the long bones, eye defects, and dysmorphic features, once thought to be two separate disorders (Sanjad-Sakati syndrome and Kenny-Caffey syndrome type 1) are now known to be a single disorder

mediated by loss-of-function variants in the tubulin chaperone E gene [56]. Recently, a dominant form of Kenny-Caffey syndrome type 2 has been described, due to pathogenic variants in *FAM111A* [57,58], the function of which is not fully understood. Mitochondrial gene defects can also result in hypoparathyroidism [59,60]. X-linked recessive hypoparathyroidism has been observed in patients with variants that affect expression of *SOX3*, a transcription factor implicated in parathyroid gland development [61]. Indeed, many cases of so-called “idiopathic hypoparathyroidism” are likely related to the previously described disorders.

#### 4.4 Disorders of parathyroid hormone production or secretion

PTH is secreted and synthesized by a classic secretory pathway. The initial translation product is a prepropeptide, which requires cleavage of the amino-terminal pre- and pro-sequences before secretion. A family with autosomal dominant inheritance of hypoparathyroidism has been reported in which a missense variant Cys → Arg variant (C18R) results in an abnormal signal sequence and diminished uptake of prepro-PTH into the endoplasmic reticulum [62]. Another family with recessively inherited hypoparathyroidism has been reported in which the preprosequence is deleted by a splicing variant [63]. Also, a family with a homozygous variant resulted in secretion of a bioinactive PTH species but

with normal to elevated intact PTH levels, suggestive of PTH resistance [64].

Parathyroid glands with normal anatomic structure may fail to secrete PTH appropriately if calcium sensing is altered. The gene for the CaSR (*CASR*) has been mapped to chromosome 3 [65,66]. Ionized calcium is a ligand for this receptor, and receptor occupancy suppresses PTH secretion. Numerous individuals and families with a variety of activating variants of the *CASR* have been reported; the associated condition is referred to as autosomal dominant hypocalcemia type 1 (ADH1) [67,68]. The renal expression of the mutant CaSR results in hyper-calciuria, despite the hypocalcemia, and an increased risk for nephrolithiasis has been reported in individuals harboring one of these variants. Progression to chronic kidney disease in this setting is a concern, particularly if urinary calcium excretion is not carefully monitored. An acquired autoimmune disorder, in which autoantibodies activate the CaSR, can mimic ADH1 [69,70]. Recently, activating variants in *GNA11*, the downstream G protein responsible for CaSR action, has been identified as a cause of ADH2 [71]. The phenotype is similar to ADH1, although variants in *GNA11* may also be associated with impaired growth and the earlier development of intracranial calcifications [72].

Severe hypomagnesemia is associated with suppressed parathyroid secretion as well as decreased end-organ sensitivity, resulting in hypocalcemia [73,74]. Conversely, as magnesium is also a ligand for the CaSR, hypermagnesemia inhibits PTH secretion via CaSR activation [1]. Transient suppression of PTH secretion causing hypocalcemia in neonates may also occur with maternal hypercalcemia [75].

#### 4.5 Parathyroid gland damage/destruction

The autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome (APECED), also known as autoimmune polyglandular syndrome type 1, is an autoimmune disorder characterized by early development of hypoparathyroidism in association with primary adrenal insufficiency and mucocutaneous candidiasis. The majority of affected individuals will manifest hypocalcemia by the age of 10 [76,77]. In addition to adrenal insufficiency, one-third of the patients will develop other endocrine disorders such as diabetes mellitus, pernicious anemia, or premature ovarian failure. This disorder is now known to be associated with pathogenic variants in a gene (*AIRE*) encoding an autoimmune regulatory protein containing a zinc finger motif and is a candidate transcription factor [78,79,204]. Affected individuals frequently develop numerous autoantibodies including antibodies to NACHT leucine-rich-repeat protein 5, a tissue-specific

autoantigen involved in hypoparathyroidism and primary ovarian insufficiency [80,81] as well as activating autoantibodies to the CaSR [82]. Polygenic forms of autoimmune hypoparathyroidism also occur, presenting more frequently in adults than in children, and may be associated with anti-parathyroid and CaSR autoantibodies as well [69,70,83]. Depending on the action of the specific autoantibody, PTH secretion may be impaired without true destruction of the gland.

Given the close anatomic relationship of the parathyroid glands to the thyroid, complete or near-complete extirpation of the thyroid gland as part of the management of either Graves' disease or thyroid cancer can be complicated by destruction or vascular compromise of parathyroid tissue and varying degrees of hypoparathyroidism. With increasing specialization of surgery practices, this should be a rare complication of thyroid surgery and, with experienced thyroid surgeons, occurs with a frequency of less than 10%. However, surgical complication remains the most common etiology of hypoparathyroidism in adults [45]. Even when destruction of the parathyroid glands does not occur following neck surgery, so-called "stunned" parathyroids with transient declines of  $\sim 1$  mg/dL in total serum calcium are often observed in the first 24–48 h postoperatively. This is presumably due to transient vascular or physical damage to the glands. Some surgeons treat with a brief course of calcitriol or calcium or both to protect against acute hypocalcemia immediately following surgery. Considerable variability in the degree of hypoparathyroidism following neck surgery occurs, ranging from asymptomatic reduction in parathyroid reserve to frank tetany, requiring chronic therapy with vitamin D and calcium. Although the parathyroid glands are quite resistant to radiation, transient hypoparathyroidism following radioactive iodine treatment for hyperthyroidism has been described [84]. Although uncommon, malignant metastasis to the parathyroid glands resulting in hypoparathyroidism has been reported, usually in the setting of breast cancer [85]. It has been postulated that granulomatous involvement of the parathyroids in sarcoidosis can lead to hypoparathyroidism [86]. Patients with transfusion-dependent thalassemia can develop hypoparathyroidism due to hemochromatosis secondary to deposition of iron in the glands [87]. In Wilson's disease, hypoparathyroidism can occur, presumably because of copper deposition [88]. Finally, impaired parathyroid reserve has been reported in diabetic patients with uremia [89].

#### 4.6 Hypocalcemia due to resistance to the actions of parathyroid hormone

Peripheral tissue insensitivity or resistance to PTH is classically termed pseudohypoparathyroidism (PHP)

[90]. The characteristic biochemical manifestations of PHP are hypocalcemia and hyperphosphatemia, as in classic hypoparathyroidism; however, circulating levels of PTH are elevated, rather than low or undetectable. The renal tubule is the primary site of PTH resistance, although skeletal resistance may occur to variable degrees and in some cases varies with treatment status [91]. However, if the skeletal response to PTH is normal, lesions characteristic of hyperparathyroidism, including osteitis fibrosa cystica, can develop [92,93].

Normally, PTH stimulates renal cAMP production, and levels of cAMP increase in the urine following administration of the hormone. A direct correlation has been demonstrated between the degree of PTH resistance (as assessed by the failure of urine cAMP excretion or phosphate to change) and the ambient circulating PTH level [94]. This renal cAMP response provides the basis for a diagnostic test that allows partial classification of this heterogeneous group of disorders. Individuals with PHP that demonstrates a blunted urinary cAMP response have PHPI. Those that generate a normal cAMP response have PHPII.

PHPI has been further characterized into types Ia, Ib, and Ic. Type Ia describes those individuals with the Albright's hereditary osteodystrophy (AHO) phenotype, which includes short stature and large frame, broad faces, and shortened fourth metacarpals, and soft tissue calcifications. These individuals often have a pathogenic variant in *GNAS*, the  $\alpha$  subunit of the stimulatory guanine nucleotide-binding regulatory protein,  $Gs\alpha$  [95]. This regulatory protein couples membrane receptors to adenylate cyclase, thereby regulating receptor-dependent cAMP production. The presence of  $Gs\alpha$  in various cell types accounts for the generalized hormone resistance that may occur. For example, affected patients often have elevated thyrotropin (TSH) levels. Variable degrees of gonadotropin, antidiuretic hormone, adrenocorticotropin, growth hormone releasing hormone, and glucagon resistance have been described [96]. Patients also have early-onset obesity and reduced insulin sensitivity [97,98]. *GNAS* and adjacent genes are imprinted, resulting in expression of only the maternal allele in certain tissues (e.g., proximal renal tubule) and biallelic expression in other (e.g., bone, distal renal tubules). Thus, the inactivating variant must be evident in the maternal allele for the expression of the classic PHPIa phenotype, where PTH-mediated effects at the proximal tubule are blunted while renal calcium reabsorption at the distal tubule is undisturbed [99]. Individuals who inherit the mutant *GNAS* from their father do not have hormone resistance but do demonstrate the AHO phenotype, referred to as pseudopseudohypoparathyroidism (PPHP), suggesting that biallelic expression is necessary in certain skeletal tissues. Of note, obesity and insulin resistance are not seen in PPHP [97,98], thereby

associating those aspects of the PHPIa phenotype with expression of the maternal allele.

PHPIb refers to individuals with PTH resistance without the AHO phenotype. These patients lack generalized resistance to most other hormones, although TSH resistance may be present [100] and a case with short metatarsals has been reported [101]. Unlike PHPIa, PHPIb is not due to inactivating variants in *GNAS*. The *GNAS* locus contains three transcripts that encode expressed proteins and two noncoding transcripts that are regulated by a complex interaction of alternative splicing and imprinting [102]. In familial cases of PHPIb, variants on the maternal allele upstream of *GNAS* in control element genes such as *STX16* or *NESP55* result in abnormal imprinting and reduced  $Gs\alpha$  activity in the proximal renal tubules [99]. Sporadic PHPIb may also be due to loss of imprinting in differentially methylated regions within the *GNAS* complex or paternal uniparental disomy of 20q. Other genetic and epigenetic changes may alter the function of the protein in different tissues [103].

Patients phenotypically and biochemically identical to PHPIa, who demonstrate normal  $Gs\alpha$  protein activity in vitro, have been classified as having PHPIc. While the genetic cause in the majority of cases currently remains unknown, studies in patients with PHPIc have identified variants in exon 13 of *GNAS*, resulting in abnormal receptor coupling [104] or other epigenetic alterations [105]. Thus, it appears that variants in *GNAS* or in neighboring regions that may affect its imprinting can cause a spectrum of defects seen in type I PHP, and an overlap between the subcategories of Ia, Ib, and Ic is likely to exist. Additionally, pathogenic variants in *PRKARIA*, which encodes the regulatory subunit of protein kinase A, and *PDE4D*, which encodes phosphodiesterase type 4, cause acrodysostosis, a rare skeletal disorder that may also exhibit PTH resistance and has features overlapping with PHPIa [106–108]. Therefore, a new classification system has been recently proposed under the umbrella of inactivating PTH/PTHrP signaling disorders [109].

In contrast to type I PHP, type II PHP is characterized by isolated resistance to the phosphaturic effects of PTH, while cAMP generation in response to PTH administration is normal. It has been suggested that this is due to variable defects distal to cAMP generation in the cascade of hormone action. AHO is absent, and no distinct skeletal phenotype is evident; various autoimmune findings have been described in some patients. This entity is quite rare, and some have questioned whether it exists as a distinct entity. It has been postulated that PHP II is a variant of severe vitamin D deficiency with associated PTH resistance because there have been numerous cases of reporting return of PTH sensitivity following vitamin D and calcium replacement [110,111].

## 4.7 Hypomagnesemia

Magnesium is necessary for release of stored PTH, and thus, magnesium deficiency can interfere with parathyroid secretion and function [73,74]. Serum magnesium levels are usually moderately to severely depressed (below the range of 1.0–1.4 mg/dL) before this occurs. Despite hypocalcemia, PTH levels may be inappropriately low or only modestly elevated, and tetany refractory to calcium supplementation can ensue. Hypomagnesemia, per se, may cause tetanic symptoms, but concomitant hypocalcemia is frequently present. Insufficient PTH secretion is the most widely accepted cause of refractory hypocalcemia in magnesium deficiency [73], although resistance to the calcemic actions of PTH and vitamin D may also play a role [112]. Impairment of vitamin D synthesis may also contribute [113]. Because PTH stimulates conversion of 25(OH)D to 1,25(OH)<sub>2</sub>D, the functional hypoparathyroidism seen with severe hypomagnesemia may result in low circulating 1,25(OH)<sub>2</sub>D levels, further compromising the body's defense against hypocalcemia [114]. Hypomagnesemia can be seen in the settings of chronic gastrointestinal disease or nutritional deficiency, especially in alcoholics. To further complicate matters, vitamin D deficiency is often present in hypomagnesemic patients [115]. Replenishment of magnesium stores promptly and restores parathyroid function to normal.

Hypomagnesemia may result from inherited disorders of magnesium excretion and/or absorption [116] and can also be induced by the renal tubular effects of several drugs, including amphotericin B, aminoglycoside antibiotics, chemotherapeutic agents (particularly cis-platinum), diuretics, and cyclosporin. Primary disorders of magnesium wasting, due to variants in the *TRPM6* ion channel, claudin family members *CLDN16* (paracellin), *CLDN19*, and in the NaCl cotransporter *SLC12A3*, may have associated defects in renal tubular handling of calcium [116]. Thus, factors other than the effect of hypomagnesemia on PTH secretion/action may play a role in the hypocalcemia often accompanying this group of disorders.

## 5. Parathyroid hormone—-independent hypocalcemia

Despite normal PTH function and downstream signaling from its receptor, hypocalcemia can still occur due to disturbances in skeletal homeostasis, vitamin D metabolism, and a variety of medical illnesses.

### 5.1 Neonatal hypocalcemia

The newborn infant undergoes an acute transition to independently regulated mineral homeostasis at

parturition. When the maternal source of calcium is eliminated, the infant's circulating calcium level transiently decreases, with recovery occurring by the third day postpartum. Infants of diabetic or preeclamptic mothers and infants who suffer perinatal asphyxia or other fetal complications may experience an exaggerated fall in serum calcium with a delayed recovery phase. Management with intravenous calcium supplementation is required for symptomatic hypocalcemia or when severely low serum calcium levels are detected. This condition is referred to as "early neonatal hypocalcemia" and is usually transient. It may be associated with transient hypomagnesemia.

Hypocalcemia presenting at 5–10 days of life is referred to as "late neonatal hypocalcemia," occurring when the serum calcium is < 8 mg/dL in a term infant or < 7 mg/dL in a preterm infant (normal range in neonates and infants is approximately 9–11.3 mg/dL [117], significantly higher than older children and adults). Many of the genetic disorders of PTH deficiency, PTH resistance, hypomagnesemia, and vitamin D metabolism described elsewhere in this chapter present during this time. Reversible forms of neonatal hypocalcemia include increased phosphate load (see below), vitamin D deficiency (see later), hypomagnesemia (see before), citrate sequestration associated with blood transfusions, and alkalosis due to hyperventilation or bicarbonate therapy [75,117]. Mild to moderate neonatal hypocalcemia commonly occurs in patients with congenital heart disease [118] and in some cases can be attributed to transient impairment of parathyroid function.

### 5.2 Nutritional vitamin D deficiency

Vitamin D synthesis in the skin requires adequate exposure to ultraviolet light. Thus, vitamin D deficiency is less common in settings where sunlight exposure is abundant. In extremes of latitude (e.g., northern climates in North America) and where industrial pollution can interfere with transmission of UV light, normal vitamin D status is dependent on adequate dietary vitamin D intake. Supplementation of milk products with vitamin D has significantly reduced the incidence of vitamin D deficiency in North America. Despite these measures, certain populations are at significant risk for development of vitamin D deficiency, and severe hypocalcemia may be a presenting manifestation of the disorder (see Chapter 62 and Chapter 63).

A convergence of several risk factors for vitamin D deficiency occurs in breastfed infants during the first 18 months of life. Breastfed infants present with vitamin D deficiency most commonly during the winter or early spring in northern US cities. The limited direct sunlight

exposure during the winter season is a major factor. Individuals with darker skin are at greater risk due to the greater quanta of UV light required to penetrate the pigmented dermis and induce previtamin D formation [119]. Breast milk contains only small amounts of vitamin D, even when the mother is receiving pharmacological doses of the vitamin. Moreover, dietary practices, including vegetarian and high grain intake, may place infants at greater risk for the development of this condition [120]. Another group at high risk for development of vitamin D deficiency is found at the other extreme of life, the elderly because of general nutritional compromise and limited sunlight exposure.

Biochemical findings in these conditions vary with the severity or duration of deficiency. The circulating 25(OH)D level is generally used to assess total body vitamin D status; however, the definition of vitamin D deficiency is highly controversial. Serum calcium levels in moderate vitamin D deficiency are often normal, compensated by secondary elevations in PTH [121]. In severe vitamin D deficiency, however, overt hypocalcemia can occur, despite elevated circulating PTH. Serum phosphate levels tend to be slightly low or normal. Circulating alkaline phosphatase activity of bone origin is usually markedly elevated in children and can be elevated in adults. Bone symptoms (pain, leg-bowing in children) may persist after periods when 25(OH)D levels have been low, even while blood levels of 25(OH)D have normalized. In children, radiographs of rachitic extremities imaged after therapy has begun can reveal several distinctive features including hyperdense lines of remineralization at the physes, consistent with recent exposure to vitamin D, despite the continuing presence of physical findings of rickets. Circulating 1,25(OH)<sub>2</sub>D levels may be low, normal, or elevated during vitamin D deficiency. This may appear paradoxical, but it should be recognized that 1,25(OH)<sub>2</sub>D circulates in nearly 1000-fold lower concentrations than 25(OH)D. Furthermore, in the setting of vitamin D deficiency, production of 1,25(OH)<sub>2</sub>D is maximized. Thus, efficient conversion of small amounts of newly ingested or synthesized 25(OH)D may markedly increase the circulating 1,25(OH)<sub>2</sub>D concentration. An intriguing paradox in this setting is the continued malabsorption of calcium, despite normal concentrations of 1,25(OH)<sub>2</sub>D; recent data have shown that ambient reduction in calcium may suppress VDR expression, which may contribute to this phenomenon [122].

The skeletal consequence of isolated severe vitamin D deficiency in children is rickets, a disorder of the epiphyseal growth plate, characterized by the expansion of the hypertrophic zone of epiphyseal chondrocytes with subsequent disorganization and expansion of the growth plate cartilage matrix [123]. The defective mineralization processes ultimately result in deformities of the long bones. In adult bone, vitamin D deficiency causes

osteomalacia, which is characterized histomorphometrically by excess undermineralized osteoid and a markedly delayed mineralization rate. Adults with osteomalacia may suffer painful pseudofractures, particularly in weight-bearing long bones.

### 5.3 Vitamin D malabsorption

Because vitamin D is a fat-soluble vitamin, generalized fat malabsorption may result in vitamin D deficiency. Gastrointestinal disorders such as Crohn's disease, celiac disease, and pancreatic insufficiency can be accompanied by hypocalcemia due to vitamin D malabsorption [124]. In addition, interruption of the enterohepatic circulation of both 25(OH)D and 1,25(OH)<sub>2</sub>D may lower body vitamin D stores. The possibility that the diseased bowel may not be able to respond to 1,25(OH)<sub>2</sub>D may also contribute to calcium malabsorption in these settings. Mild hypocalcemia and secondary hyperparathyroidism are also seen in cholestatic liver diseases such as primary biliary cirrhosis. In the setting of low albumin, circulating levels of vitamin D–binding protein, total 25(OH)D, and free 25(OH)D are reduced in liver disease; 25(OH)D levels may not necessarily confirm adequate vitamin D status in liver disease [125]. It is not clear whether 25-hydroxylase (25-OHase) activity is significantly diminished in liver disease, although most reports suggest that the diseased liver retains the capacity for 25-hydroxylation when there is adequate substrate, except in situation of extreme liver failure [126]. Similarly, pathogenic variants in the gene encoding 25-OHase are a rarely reported cause of vitamin D–dependent rickets [127–130]. Liver transplantation typically improves vitamin D status, although immunosuppressive drugs may continue to have an adverse effect on calcium and vitamin D metabolism [131,132].

## 6. Genetic forms of vitamin D–dependent rickets

### 6.1 Deficiency of 1 $\alpha$ -OHase

Impaired metabolism of 25(OH)D to 1,25(OH)<sub>2</sub>D is characterized by hypocalcemia and severe rickets [130]. The disorder (also termed pseudo-vitamin D–deficient rickets or vitamin D–dependent rickets, type 1) is inherited in an autosomal recessive manner and is characterized by biochemical features similar to those of vitamin D–deficient rickets, with the exceptions that circulating 25(OH)D levels are normal and circulating 1,25(OH)<sub>2</sub>D levels are low (see Chapter 66). Loss-of-function variants in the gene encoding the ferredoxin-binding component of the mitochondrial P450 enzyme, 1 $\alpha$ -OHase (*CYP27B1*) or hepatic 25-hydroxylase (*CYP2R1B*), have been shown to cause

this condition [130,133]. Restoration of eucalcemia and correction of rickets are attainable with physiological doses of  $1,25(\text{OH})_2\text{D}$  [134].

## 6.2 Hereditary resistance to $1,25(\text{OH})_2\text{D}$

A defect in target-tissue responsiveness to  $1,25(\text{OH})_2\text{D}$  was clinically described shortly after the capacity to measure circulating  $1,25(\text{OH})_2\text{D}$  became available. Patients with hypocalcemia due to  $1,25(\text{OH})_2\text{D}$  resistance have severe manifestations of vitamin D-deficient rickets, despite normal serum  $25(\text{OH})\text{D}$  concentrations and elevated serum levels of  $1,25(\text{OH})_2\text{D}$ . This disorder is usually inherited in an autosomal recessive manner. Additional features in many patients include alopecia totalis and oligodontia [135].

The disease is variably responsive to large doses of  $1,25(\text{OH})_2\text{D}$  and oral calcium therapy. In the most resistant cases, long-term parenteral calcium infusions can normalize serum chemistries and cure the skeletal lesions [136]. The positive therapeutic response to parenteral calcium suggests that mediation of calcium absorption at the intestine is the critical systemic action for  $1,25(\text{OH})_2\text{D}$ .

There are several defects in the coding region of the VDR, which impair or prevent either hormone or DNA binding. Reduced levels of the VDR and variants in the gene encoding heterogenous nuclear ribonucleoprotein C (*HNRNPC*), a VDR coactivator, have also been described [137,138] (see Chapter 68).

## 6.3 Genetic causes of increased vitamin D metabolism

Recently an autosomal dominant form of genetic vitamin D deficiency rickets has been described; it is due to a gain-of-function variant *CYP3A4*. This encodes a P450 enzyme that metabolizes many xenobiotics and drugs, leading to vitamin D deficiency through accelerated vitamin D metabolite inactivation. The result of this variant is similar to adverse effects of drugs that are potent inducers of *CYP3A4* activity, such as rifampin, leading to vitamin D deficiency [139] (see Chapter 67).

## 7. Dietary calcium deficiency

Although uncommon, extremely low calcium intakes have been reported to be associated with mild hypocalcemia. Nigerian and South African children with calcium intakes of 150 mg/day or less were found to have reduced serum calcium values, secondary hyperparathyroidism, and rickets [140] without vitamin D

deficiency. Studies using stable calcium isotopes have demonstrated that intestinal calcium absorption in this group is not impaired [141] and children respond to treatment with calcium alone better than vitamin D alone, even when there is mild coincident vitamin D deficiency [142]. Similar findings have been observed in certain US populations. This phenomenon appears to occur after children have been weaned to diets with little to no dairy product content, with fluids consisting mostly of juices and soft drinks [143]. Thus, nutritional rickets may reflect calcium or vitamin D deficiency and often some combination of the two, given the common dairy source of these nutrients.

## 8. Hyperphosphatemia-mediated hypocalcemia

Since the 1930s, it has been appreciated that oral or parenteral phosphate can induce a decline in serum calcium concentrations. Hebert et al. have demonstrated that phosphate infusions lower serum calcium in both the presence and absence of parathyroid glands [144]. Moreover, they reported that the changes in peak urinary calcium excretion during phosphate administration are not sufficient to account for the fall in the serum calcium. The theory they advanced to explain this phenomenon centers on the hypothesis that the calcium  $\times$  phosphate molar product, when exceeded, leads to spontaneous precipitation of calcium salts in soft tissues. The biophysical mechanisms of soft tissue calcification are substantially more complex than invoked by this hypothesis or that can be detailed here. Nevertheless, clinical guidelines have been provided for use in patients with chronic kidney disease. While historically, the National Kidney Foundation KDOQI Guidelines recommended that the  $\text{Ca} \times \text{P}$  product be considered as a risk factor for extra-skeletal calcifications, more recent data suggest that this is not a well-validated marker [145,146].

Hyperphosphatemia sufficient to cause hypocalcemia is usually abrupt in onset and severe in magnitude. Typical clinical settings include (1) Excessive enteral or parenteral phosphate administration, (2) The tumor lysis syndrome, and (3) Rhabdomyolysis-induced acute renal failure. Hypocalcemia induced by phosphate administration is often associated with soft tissue calcification. Such ectopic calcification has been observed during the treatment of hypophosphatemia due to either diabetic ketoacidosis or acute alcoholism. Individuals receiving phosphate-containing enemas and infants fed “humanized” cow milk rich in phosphate may also become hypocalcemic [147,148]. Under most circumstances, discontinuation of exogenous phosphate intake leads to prompt return of the serum calcium level to normal.

Hypocalcemia in the setting of massive tumor lysis results from the release of intracellular phosphate

because of chemotherapy-induced cell death, usually during the treatment of rapidly proliferating neoplasms [149]. The hypocalcemia may continue beyond the period of hyperphosphatemia and appears to be aggravated by suppressed  $1,25(\text{OH})_2\text{D}$  levels [150]. The use of phosphate-binding antacids, oral calcium, and, in severe cases,  $1,25(\text{OH})_2\text{D}$  may help to correct the serum calcium level.

Rhabdomyolysis-induced acute renal failure occurs with trauma and drug or alcohol abuse. Marked hypocalcemia can occur in the early oliguric phase and moderate to severe hypercalcemia in the subsequent polyuric phase. Llach et al. have described hyperphosphatemia and suppressed serum  $1,25(\text{OH})_2\text{D}$  levels during the initial hypocalcemic phase, suggesting a mechanism similar to that seen in the tumor lysis syndrome [151]. The appearance of hypercalcemia and high serum  $1,25(\text{OH})_2\text{D}$  levels during the diuretic phase may result from rapid development of secondary hyperparathyroidism during the initial hypocalcemic period. Treatment includes restriction of phosphate intake and efforts to prevent hypocalcemia during the early stages of the disease.

## 9. Hypocalcemia due to accelerated skeletal mineralization

Bone remodeling is a controlled process of tissue renewal that, in healthy individuals, results in closely matched rates of bone resorption and formation. When skeletal mineralization exceeds the rate of bone resorption in the absence of sufficient ambient calcium, hypocalcemia can occur. One setting in which this can be observed is following surgical correction of primary or tertiary hyperparathyroidism. The abrupt cessation of PTH-mediated osteoclastic bone resorption with concomitant rapid remineralization of an under-mineralized skeleton can lead to “hungry bone syndrome” with severe, even life-threatening hypocalcemia [152]. Postoperative treatment should be instituted when the serum calcium level falls below 8.0 mg/dL, using oral or parenteral calcium supplements and calcitriol. In general, this condition resolves over the course of several days, although distinguishing it from permanent postoperative hypoparathyroidism can be difficult and requires gradual discontinuation of supportive therapy with careful monitoring. Patients with primary hyperparathyroidism who are taking cinacalcet should have their drug stopped several days before parathyroid surgery to reduce the risk of postoperative hypocalcemia. A phenomenon resembling the hungry bone syndrome has been observed when PTH 1–34 therapy is discontinued in hypo-parathyroid patients [153]. Hypocalcemia also may occur in patients with bony

metastases that induce bone formation, as with prostatic and breast cancer [154]. Finally, institution of therapy for vitamin D–deficient osteomalacia or rickets can sometimes lead to a fall in serum calcium associated with rapid mineralization of previously un-mineralized osteoid [155]. This is self-limited and can usually be prevented with supplemental calcium.

## 10. Medical illness

Several medical conditions are complicated by hypocalcemia. Decreased circulating calcium in the setting of renal failure results from hyperphosphatemia due to reduced renal phosphate clearance by the failing kidney and is complicated by impaired biosynthesis of  $1,25(\text{OH})_2\text{D}$  [156]. Hypocalcemia and tetany were first reported in patients with pancreatitis in the early 1940s [157]. Pancreatic lipase released from the damaged gland is believed to liberate free fatty acids that chelate calcium, thereby removing it from the extracellular fluid [158].

Hypomagnesemia resulting from poor oral intake, alcohol use, or vomiting may contribute to the hypocalcemia. Hypocalcemia in the setting of pancreatitis often suggests a poor clinical course [159]. In addition to increased skeletal mineralization, hypocalcemia in malignancy can be associated with numerous other factors, including cancer therapies and comorbid conditions [160].

Hypocalcemia may also occur in patients with acute sepsis [161]. In one series, 20% of such patients evidenced reductions in ionized serum calcium [162]. Hypocalcemia in this series was associated with a poor prognosis (50% mortality, compared with 30% in eucalcemic patients). This phenomenon is most often reported with gram-negative sepsis but has occurred in toxic shock syndrome caused by staphylococcal infection [163]. The hypocalcemia seen in meningococcal septicemia may be due to acute extravasation of calcium into the subcutaneous tissues [164]. Pro-inflammatory cytokines may also upregulate the CaSR, resulting in decreased PTH secretion and hypocalcemia [165].

Finally, it has been suggested that parathyroid gland reserve is subnormal in patients with AIDS, although hypocalcemia is not a prominent feature of that disorder [166].

### 10.1 Medications

A variety of medications have been reported to decrease serum-ionized calcium concentration. Many of these drugs are used to treat hypercalcemia and/or excessive bone resorption, and hypocalcemia results from their overzealous use. Thus, mithramycin, calcitonin, bisphosphonates, and denosumab can all cause hypocalcemia. In susceptible individuals, prolonged

therapy with diphenylhydantoin or phenobarbital can lead to hypocalcemia, owing in part to enhanced catabolism of vitamin D metabolites [167]. Citrated blood products, particularly when used for large-volume transfusions or plasma plasmapheresis, can cause hypocalcemia [168]. Radiocontrast agents that contain ethylenediaminetetraacetic acid can also induce falls in serum-ionized calcium levels [169]. Finally, foscarnet (trisodium phosphonoformate), used in the treatment of cytomegalovirus ocular infections and acyclovir-resistant herpes, has been reported to cause a decline in ionized serum calcium, perhaps through complexing extracellular calcium [170].

## 11. Treatment of hypocalcemia

### 11.1 Acute management

#### 11.1.1 Newborns and children

It may be necessary to treat early neonatal hypocalcemia. Appropriate emergency therapy of acute symptomatic hypocalcemia consists of a slow intravenous infusion of 10% calcium gluconate. One gram of 10% calcium gluconate is 1000 mg/10 mL; 9.3% of that is elemental calcium. Thus, there are 93 mg of elemental calcium in 10 mL of 10% calcium gluconate. For tetany or seizures, 1–3 mL can be given via slow intravenous push over 5–10 min with no more than 2 mg of elemental calcium per kilogram body weight given as a single dose. A well-functioning indwelling intravascular catheter should be used to avoid extravasation. Calcium should never be administered intramuscularly because of local tissue toxicity. It is important to perform cardiac monitoring and careful observation during acute infusions. Bolus infusions may be repeated at a slower rate up to 4 times in a 24 h period. If severe hypocalcemia persists, however, it is generally more effective to use a long-term calcium gluconate infusion, such that 20–50 mg of elemental calcium per kilogram body weight is infused over an entire 24 h period. Dosing for infants and older children is similar. Calcium chloride is more irritating than calcium gluconate and is not the preferred salt for infusion; it should never be administered through a peripheral vein. Neither bicarbonate nor phosphate should be co-infused with calcium to prevent precipitation of their respective calcium salts, either in the infusion line or in the vein.

#### 11.1.2 Adults

In adults, emergency management consists of 10–20 mL of 10% calcium gluconate infused over a 10–15 min period. In the longer term, one can dilute 100 mL of 10% calcium gluconate (representing 930 mg

of elemental calcium) in 1 L of 5% dextrose or normal saline and, beginning at a rate of 50 mL/h, titrate the rate to maintain the serum calcium in the low normal range. Typically, a dose of ~ 1.25 mg elemental calcium/kg body weight/hour is sufficient. As before, if only calcium chloride is available, a central line must be used for administration. It is important to monitor the patient's EKG during calcium infusions for adverse cardiac effects such as excessive shortening of the corrected QT interval or bradyarrhythmias. Finally, in the setting of acute exacerbations of calcium malabsorption, as may typically occur in patients with autoimmune hypoparathyroidism with associated gastrointestinal disorders, nocturnal nasogastric supplementation with calcium carbonate or calcium glubionate has been employed, providing up to 20 mg of elemental calcium per kilogram body weight per 8 h, as necessary, until the underlying intestinal disturbance has resolved.

#### 11.1.3 Role of magnesium supplementation

In the setting of hypomagnesemia, magnesium therapy may be required to restore PTH secretion and sensitivity of target tissues to the hormone. Prior to administration of magnesium salts, assessment of renal function and urinary output should be performed. Magnesium treatment in infancy consists of 5–10 mg of elemental magnesium per kilogram body weight. Although magnesium may be given intramuscularly, the intravenous route is preferred. Magnesium sulfate heptahydrate ( $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ ) is available as a 50% solution, containing 48 mg/mL of elemental magnesium. These small volumes may be further diluted, but they should be infused slowly; the dose may be repeated every 12–24 h. In older individuals, up to 2.4 mg of elemental Mg per kilogram body weight can be given over a 10 min period (to a maximum of 180 mg). Others prefer a continuous infusion of 576 mg of elemental magnesium over 24 h. The length of therapy must be individualized, and maintenance with oral magnesium salts should be implemented in cases where ongoing hypomagnesemia is anticipated.

Magnesium levels should be monitored to avoid toxicity. Deep tendon reflexes can be examined, and therapy should be halted if they diminish. As with calcium therapy, cardiac monitoring should be performed and therapy should be stopped if EKG changes occur. Intravenous calcium gluconate is a useful antidote for magnesium intoxication and should be available at the bedside.

### 11.2 Long-term management

Many of the causes of hypocalcemia discussed before are corrected by treating the underlying disorder (e.g.,

vitamin D deficiency, tumor lysis syndrome, hypomagnesemia disorders). Management of patients with chronic kidney disease is complex and varies depending on the degree of renal insufficiency; treatment may involve a combination of calcium, phosphate binders, vitamin D analogs, and calcimimetics [171]. Of those disorders requiring maintenance therapy for hypocalcemia, the most important are hypoparathyroidism, PHP, and inborn errors of vitamin D.

### 11.3 Hypoparathyroidism

In hypoparathyroidism, the distal tubule lacks the PTH signaling necessary for appropriate renal calcium reabsorption. Thus, serum calcium should be maintained at or slightly below the lower limit of the age-specific normal range to avoid hypercalciuria and nephrocalcinosis. Treatment should be titrated to reduce symptoms, such as circumoral tingling, paresthesia, and carpopedal spasm. Conventional therapy includes the combination of a vitamin D metabolite with calcium supplements, given in divided doses throughout the day [172]. A wide variety of preparations of both are available. The amount of elemental calcium varies based on preparation (Table 65.2). Because of the prolonged toxicity that occurs with excessive ingestion of calciferol, many prefer to use rapid-acting preparations of vitamin D (calcitriol, alfacalcidol), particularly in children. Toxicity, when it occurs with these latter preparations, corrects more rapidly with discontinuation of the drug. However, high doses of ergocalciferol or cholecalciferol can be used effectively, particularly in patients with poor compliance or concurrent mal-absorptive disorders, such as celiac disease or APECED. The dose of calcitriol typically ranges from as little as 0.25 up to 2.0 µg/day [173,174]. When higher doses are needed, calcitriol should be dosed twice daily because its biological half-life is approximately 12–14 h. Hypercalcemia, when it

develops during therapy with calcitriol, usually resolves within 3–4 days after discontinuing the drug.

High dietary calcium is generally recommended with the caveat that this should not come solely from dairy products, which also contain large amounts of phosphate. Phosphate-restrictive diets and phosphate binders are not routinely used. Most patients require additional calcium supplementation; 1000–2500 mg/day of elemental calcium in divided doses may be necessary. As enteral calcium supplements will reduce serum phosphate while vitamin D preparations will increase intestinal phosphate absorption, it is often preferable to first increase the calcium dose before adjusting the calcitriol dose. Commercially available calcium salts include carbonate, citrate, lactate, gluconate, and glucobionate. Calcium carbonate is 40% elemental calcium, inexpensive, well tolerated, and easily acquired. Patients are generally instructed to take it with food as gastric acidity appears to be required for absorption. However, the effects of acid-blocking medications on calcium absorption continue to be controversial [175,176]. Of note, many patients with hypoparathyroidism are also hypothyroid; as calcium decreases the absorption of levothyroxine, the timing of these medications should be separated. In some cases of hypoparathyroidism, a thiazide diuretic may be useful in augmenting serum calcium levels and reducing the hypercalciuria that can occur with the institution of treatment [177], although hypokalemia is an untoward side effect that should be closely monitored. However, the use of thiazides in hypoparathyroidism treatment has not been systematically tested. Likewise, a low-sodium diet may also reduce the risk of hypercalciuria, but this has not been well studied. There are many limitations of conventional therapy, specifically wide fluctuations in serum calcium, high pill burden, poor quality of life, and renal complications.

Magnesium deficiency can occur in patients with hypoparathyroidism, most often in patients with autosomal dominant hypocalcemia [178] or secondary to steatorrhea, which is seen in the autoimmune forms of this disorder [179,180]. This may render a patient relatively resistant to therapy, and therefore, magnesium deficiency should be considered in individuals whose therapeutic requirements unexpectedly increase. Symptoms of hypomagnesemia are similar to those of hypocalcemia, with some patient reporting decrease in symptoms when magnesium is added to their regimens.

PTH replacement therapy may improve the biochemical profile in those in whom conventional therapy is not adequate. Inadequate control may be due to symptomatic hypocalcemia, hyperphosphatemia, renal insufficiency, hypercalciuria, or poor quality of life. PTH replacement therapy for hypoparathyroidism has been under investigation since the mid-1990s, initially with the PTH 1–34 fragment, known as teriparatide and

**TABLE 65.2** Percentage of elemental calcium in different calcium salts.

	% Elemental calcium
Calcium acetate	25
Calcium carbonate	40
Calcium chloride	27
Calcium citrate	21
Calcium glucobionate	6.4
Calcium gluconate	9
Calcium lactate	13
Calcium phosphate, tribasic	39

more recently with intact PTH 1–84. Numerous studies have demonstrated that, in most pediatric and adult patients, the hypocalcemia can be adequately controlled with once or twice daily subcutaneous injections of PTH 1–34 or PTH 1–84, in some cases with patients receiving no supplemental calcium or calcitriol [181–183]. In a short-term placebo-controlled study of PTH 1–84, blood phosphate levels were also reduced, which may decrease the risk of extra-skeletal calcifications [184]. While most studies have failed to show persistent improvement in 24 h urine calcium excretion, a long-term open-label extension of this study did demonstrate reduction of mean 24 h urine calcium excretion into the normal range [185]. Of note, twice-daily PTH 1–34 induced significant hypo-citraturia, with 51% of patients developing new or worsening nephrocalcinosis or nephrolithiasis on imaging [186]. In the 6 year study by Rubin et al., 3 out of 33 subjects developed clinical nephrolithiasis in the final years of treatment [183].

In addition to the questionable effects on the kidney, the long-term skeletal effects of intermittent subcutaneous PTH therapy are unknown. Both PTH 1–34 and PTH 1–84 stimulate bone turnover dramatically, markedly increasing formation and resorption markers with persistent elevations maintained after several years of therapy [181,183,185,187]. Bone densitometry and iliac crest bone biopsies reveal the paradoxical skeletal actions of PTH therapy, with anabolic effects resulting in increased trabecular bone volume and catabolic effects evidenced as increased cortical porosity and decreased radial bone density [153,183,185,188]. Whether changes in bone with this exposure are transient is unknown; however, some data suggest that continued PTH therapy may restore the skeleton to normal [189,190]. Due to high bone turnover state induced, PTH therapy should not be abruptly discontinued but rather weaned slowly with concomitant administration of high doses of calcium and calcitriol to prevent severe, life-threatening hypocalcemia, similar to the hungry bone syndrome observed after parathyroidectomy in patients with hyperparathyroidism [153].

Subcutaneous recombinant full-length PTH 1–84 was approved in the United States in 2015 for the treatment of adults with hypoparathyroidism who cannot be adequately controlled with active vitamin D and calcium supplements [191] but was removed from the market in 2019 due to manufacturing issues. In November 2020, the US Food and Drug Administration (FDA) removed the “black box” warning indicating potential risk of osteosarcoma for teriparatide (PTH 1–34), which has been approved for osteoporosis but not hypoparathyroidism. While it is unclear whether intermittent subcutaneous PTH (1–34), teriparatide, is able to

prevent long-term complications in chronic hypoparathyroidism, replacement therapy with multiple daily injections of teriparatide appears to be effective at managing hypocalcemia for up to 10 years [192]. Recently, a phase 2, randomized, double-blind, placebo-controlled 4 week trial of TransCon PTH, an investigational long-acting prodrug of PTH(1–34), followed by an open-label extension, demonstrated significant reduction in oral active vitamin D and Ca requirements for most participants. Participants achieved normal serum calcium, serum phosphate, urine calcium, serum calcium-phosphate product, and improved health-related quality of life [193,194]. Small, short studies have suggested that continuous subcutaneous infusion of PTH may be more physiologic than intermittent injections [195,196]. Finally, development of new drugs including long-acting PTH analogs [197], PTH-related protein analogs, PTH receptor modulators [198], and allosteric modulators of CaSR [199] all hold promise that better therapies are yet to come.

Magnesium deficiency can occur in patients with hypoparathyroidism, most often in patients with autosomal dominant hypocalcemia [178] or secondary to steatorrhea, which is seen in the autoimmune forms of this disorder [179,180]. This may render a patient relatively resistant to therapy, and therefore, magnesium deficiency should be considered in individuals whose therapeutic requirements unexpectedly increase. Symptoms of hypomagnesemia are similar to those of hypocalcemia, with some patients reporting a decrease in symptoms when magnesium is added to their regimens.

### 11.4 Pseudohypoparathyroidism

In PHP, the medications used are the same, but the goals of therapy are different. The skeleton in patients with PHP is often responsive to the ambient hyperparathyroidism; thus, treatment is aimed at normalizing the PTH to decrease the risk of hyper-parathyroid bone disease, including osteoporosis and osteitis fibrosa cystica, as well as tertiary hyperparathyroidism [92,93,200]. This requires maintenance of the serum calcium level well within the normal range. As distal renal tubular calcium reabsorption remains responsive to PTH, hypercalciuria and nephrocalcinosis are extremely rare in these patients but can occur when overtreatment results in hypercalcemia and PTH suppression. Untreated patients with PHP may have varying degrees of osteopenia and initially may require high-dose therapy to achieve eucalcemia as their bones re-mineralize. Requirements will decrease as the bone heals, often heralded by a fall in serum alkaline phosphatase and a rise in serum calcium levels.

## 11.5 Genetic forms of vitamin D–dependent rickets

Individuals with 1 $\alpha$ -OHase deficiency have a defect in the ability to generate 1,25(OH)<sub>2</sub>D from the precursor metabolite 25(OH)D. In this disorder, eucalcemia can be achieved by supplying 1,25(OH)<sub>2</sub>D in physiological dosages [134]. In contrast, patients with hereditary resistance to 1,25(OH)<sub>2</sub>D due to pathogenic variants in the VDR can present with a spectrum of resistance to calcitriol therapy, with some individuals responding to doses of calcitriol in the usual therapeutic range and others resistant to even massive doses of the drug [138]. As noted before, chronic therapy with parenteral infusions of calcium has resulted in improvement of the rickets and normalization of all serum biochemical parameter [136]. Additionally, two novel analogs (20-epi-1,25(OH)<sub>2</sub>D and JK-1626–22) have been found to be somewhat more efficacious than 1,25(OH)<sub>2</sub>D itself in the treatment of cases of hereditary resistance to vitamin D caused by pathogenic variants in the ligand-binding domain of vitamin D receptor [201].

Even with excellent patient adherence to the treatment regimen and careful monitoring, a variety of stresses including trauma, immobilization [202], infection, gastrointestinal illness, pregnancy, and lactation [203] can increase or decrease the therapeutic requirements. Thus, extra vigilance is required during those times. Providing patients with a standing laboratory order for a calcium measurement allows them to obtain blood work at the first sign of symptoms, enabling the practitioner to adjust medication doses rapidly and ideally avoiding hospitalization for a hypo or hypercalcemic crisis.

## 12. Conclusion

Hypocalcemia can be due to numerous genetic and acquired conditions, primarily related to alterations in PTH and vitamin D metabolism. Identifying the underlying etiology of hypocalcemia is important as therapeutic options and treatment goals vary depending on the cause. In the case of heritable conditions, genetic counseling of affected individuals is critical to anticipate and avoid hypo-calcemic seizures in their children, particularly newborns. Although calcium and traditional vitamin D analogs remain the mainstay of therapy for most chronic hypocalcemic conditions, newer, directed therapies are in development that will hopefully allow for precision management of patients, while avoiding the morbidities associated with conventional therapies.

## 13. Summary points

- Regulatory mechanisms maintain calcium within a narrow range by calciotropic hormones, PTH, and vitamin D.
- Hypocalcemia can be due to numerous genetic and acquired conditions, primarily related to alterations in PTH and vitamin D metabolism.
- Hypocalcemic disorders are classified by their functional etiologies and discussed in relationship to primary homeostatic disturbances including inadequate PTH secretion, resistance to PTH action, or PTH independence.
- Identifying the underlying etiology of hypocalcemia is important as therapeutic options and treatment goals vary depending on the cause.

## Acknowledgments

Work in the RIG's group is supported by the Intramural Research Program of the NIH, NIDCR.

# Vitamin D hydroxylation—deficient rickets, type 1A

*Francis H. Glorieux and René St-Arnaud*

Shriners Hospitals for Children—Canada and Department of Surgery, McGill University, Montreal, QC, Canada

## OBJECTIVES

- Present the main clinical manifestations and biochemical changes in patients with VDDR1A.
- Explain the molecular etiology of the disease and the mutations affecting patients.
- Discuss treatment alternatives and the accepted standard of care.
- Describe the impact of treatment over the course of the life of the patients.

## 1. Introduction

The term “rickets” is erroneously used to describe all of the skeletal abnormalities associated with defective mineralization in the growing skeleton, but it is more precise to restrict the term to changes in the growth plate and adjacent metaphysis. When mineralization is impaired, the accumulation of unmineralized osteoid at sites other than the growing metaphysis should be referred to as osteomalacia, not as rickets. Thus, defective mineralization can lead to both rickets and osteomalacia in the growing skeleton but only to osteomalacia in the mature skeleton.

Rickets is characterized by the inadequate calcification of the growth plate and adjacent metaphysis. The impaired mineralization of the growth plate cartilage in the zone of provisional calcification prevents this zone from being resorbed (see Chapter 62 and Chapter 63). As the cartilage continues to be formed, but not

resorbed, the growth plate begins to widen. Simultaneously, the trabecular bone directly underneath the cartilage fails to mineralize properly, and vascularization of this tissue becomes aberrant. These defects are accompanied by similar abnormalities in cortical bone, leading to the full spectrum of skeletal symptoms associated with the pathology.

“Rickets resistant to vitamin D therapy” were described clinically by Albright et al. in 1937 [1]. Subsequent reports [2,3] suggested a variant of resistant rickets that was fully clinically described by Prader et al. in 1961 [4]. The absence of knowledge of the underlying molecular etiology of these diseases led to several, somewhat confusing designations: pseudo-vitamin D deficiency rickets (PDDR) [4]; vitamin D dependency (VDD) [5]; vitamin D-dependent rickets, type I (VDDR-I); or 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase (1 $\alpha$ -OHase) deficiency [6]. In 1997, remarkable progress was made in the understanding of the molecular etiology of the disease through the identification of mutations in the gene encoding the 25-1 $\alpha$ -OHase (*CYP27B1*) in affected patients, leading to hydroxylation defects and the inability to synthesize 1,25(OH)<sub>2</sub>D [7]. For this reason, and to align with current OMIM (Online Mendelian Inheritance in Man compendium) nomenclature, we will use the OMIM designation of vitamin D hydroxylation—deficient rickets, type 1A (VDDR1A, OMIM 264700) to describe the disease.

Other genetic defects of vitamin D metabolism and action with related nomenclature include vitamin D hydroxylation—deficient rickets, type 1B (VDDR1B, OMIM 600081) (Chapter 67), caused by mutations in the *CYP2R1* gene [8–11] encoding the microsomal vitamin D 25-hydroxylase [12] and involving a defect

**TABLE 66.1** Affected genes and clinical manifestations in VDDR 1B, 1A, and 2A.

Feature	VDDR1B	VDDR1A	VDDR2A
Mutations	<i>CYP2R1</i>	<i>CYP27B1</i>	<i>VDR</i>
Genetic inheritance	Autosomal recessive	Autosomal recessive	Autosomal recessive
Age of onset	Late (4–5 years of age)	Early	Early
Rickets	Yes	Yes	Yes
Hypocalcemia	Yes	yes	Yes
Serum alkaline phosphatase	Elevated	Elevated	Elevated
Secondary hyperparathyroidism	Yes	Yes	Yes
Alopecia	No	No	Yes
Serum 25(OH)D	Low to undetectable	Normal	Normal
Serum 1,25(OH) <sub>2</sub> D	Normal/high	Low	Elevated
Response to 25(OH)D therapy	Yes	No	No
Response to 1,25(OH) <sub>2</sub> D therapy	Partial	Yes	No

**FIGURE 66.1** Height z-score according to age at time of diagnosis in young children with VDDR1A. From Ref. [14] with permission.

in vitamin D 25-hydroxylation. Vitamin D–dependent rickets type 2A (VDDR2A, OMIM 277440) (Chapter 68) is caused by mutations in the vitamin D receptor (*VDR*) gene [13]. This condition is also referred to as hereditary vitamin D resistant rickets (HVDRR). Although clinically similar, VDDR1A is characterized by extremely low to absent serum 1,25(OH)<sub>2</sub>D levels, while VDDR2A is characterized by very high levels of circulating 1,25(OH)<sub>2</sub>D (Table 66.1).

## 2. Clinical manifestations

Patients with VDDR1A are healthy at birth, and the first symptoms usually appear within the first year of life. The majority of patients (85%) present with neurological signs: delayed gross motor development and hypotonia (70%), or hypocalcemic seizures (15%). Growth retardation is a common manifestation (70%), and height at the time of diagnosis is reduced for age (Fig. 66.1). Pathological fractures may occur. In the past, when the diagnosis was either missed or made too late to intervene, infant death by hypocalcemia or pulmonary infections was frequent. A history of adequate mineral and vitamin D intake, without evidence of intestinal malabsorption, is a constant finding.

Physical examination reveals a short, hypotonic child with features of rickets. There is a wide anterior fontanel with frontal bossing and frequent craniotables (easy depression of the softened parietooccipital area). Tooth eruption is delayed, and erupted teeth show evidence of enamel hypoplasia. A “rachitic rosary” (enlargement of the costochondral junctions along the anterolateral area of the chest) is either visible or palpable. The development of a Harrison sulcus (depression on both sides of the chest wall between the pectoral muscles and the lower margin of the ribcage) caused by the muscular pull of the diaphragmatic attachments to the lower ribs can be observed. In the appendicular skeleton, enlargement of the metaphyseal areas is more evident in the wrists and ankles, and there is a variable degree

of deformity (bowing) of long bone diaphyses. The site and type of deformity of the extremities depend upon the age of the child and the weight-bearing patterns in the limbs. Thus, deformities of the forearms and anterior bowing of the distal tibia are found more commonly in infants, whereas an exaggeration of the normal physiological bowing of the legs (*genu varum*) is a characteristic finding in the VDDR1A toddler who has started to walk. The Chvostek sign (twitching of the upper lip on light finger tapping of the facial nerve) reflects nerve irritability, a consequence of a rapid drop in serum calcium.

Radiological examination of the skeleton reveals diffuse osteopenia and the classic metaphyseal changes of vitamin D deficiency. There is a fraying, cupping, widening, and fuzziness of the zone of provisional calcification immediately under the growth plate. These changes are seen better and detected earlier in the most active growth plates, namely, the distal ulna and femur and the proximal and distal tibia. Changes in the diaphyses may not be evident when metaphyseal changes are first detected. However, they will appear a few weeks later as rarefaction, coarse trabeculation, cortical thinning, and subperiosteal erosion. The latter reflects the increased resorption induced by secondary hyperparathyroidism. When performed, bone mineral density (BMD) of the lumbar spine is very low [14].

### 3. Biochemical findings

Hypocalcemia is the cardinal feature in VDDR1A. Serum calcium concentration will drop below 2 mmol/L (8 mg/dL). This, particularly if the decrease is rapid, may give rise to tetany and convulsions, which may occur prior to any radiological evidence of rickets. Persistent hypocalcemia triggers secondary hyperparathyroidism and hyperaminoaciduria [15]. Urinary calcium content is low, whereas fecal calcium is high, reflecting impaired intestinal calcium absorption.

Serum phosphate concentration may be normal or low. Hypophosphatemia, when present, is usually of a lesser degree than in X-linked hypophosphatemia. It is the result of both impairment of intestinal absorption and increased urinary loss induced by secondary hyperparathyroidism. Serum alkaline phosphatase activity is consistently elevated (over 800 IU/L). Its increase often precedes the appearance of clinical symptoms. The calcemic response to PTH is usually, but not necessarily, absent [16].

Studies of circulating vitamin D metabolites have provided a key insight into the pathogenesis of VDDR1A. Serum levels of 25(OH)D are normal in the untreated patient. These results indicate that intestinal absorption of vitamin D and its hydroxylation in the liver are not

impaired in VDDR1A. On the contrary, circulating levels of 1,25(OH)<sub>2</sub>D are low [16–18]. This is evident rapidly after birth, months before any clinical or radiological signs of rickets develop. Even when patients are treated with large doses of vitamin D, causing major increases in the circulating levels of 25(OH)D, 1,25(OH)<sub>2</sub>D levels do not reach the normal range (Fig. 66.2). This clearly identifies defective activity of the 1 $\alpha$ -OHase as the basic abnormality in VDDR1A and differentiates it from vitamin D-dependent rickets type 2A (Table 66.1). Although 1,25(OH)<sub>2</sub>D serum levels are low, in many cases they remain detectable and positively correlated to the serum concentration of 25(OH)D [17].

Circulating levels of 24,25(OH)<sub>2</sub>D are normal in VDDR1A patients and are highly correlated with those of 25(OH)D, indicating a fully functional vitamin D 24-hydroxylase (CYP24A1) enzyme [19].

### 4. Genetic and molecular studies

Animal models of VDDR1A were generated independently by three laboratories using targeted inactivation of the gene of interest in mice [20–22]. The phenotypic consequences of *Cyp27b1* inactivation in mouse preclinical models are detailed in Chapter 30.

**FIGURE 66.2** Serum 1,25(OH)<sub>2</sub>D concentrations in control children and in VDDR1A patients either untreated or treated with high doses of vitamin D or calcitriol.

VDDR1A is inherited as a simple autosomal recessive trait [5]. No phenotypic abnormalities have been observed in heterozygous carriers of mutations [23]. Although generally rare, VDDR1A may be more common in genetically isolated populations as a result of founder effects. For example, VDDR1A occurs at an unusually high frequency in the French Canadian population originating from the Charlevoix-Saguenay-Lac Saint Jean region of the province of Quebec [24,25]. This high local incidence of 1 in 2400 live births with a carrier rate of 1 in 26 [26] allowed mapping of the disease gene to chromosome 12q14 [27]. Microsatellite haplotyping identified distinct founder populations between the Charlevoix-Saguenay-Lac Saint Jean area and the eastern Canadian (Acadian) region [28]. Founder effects have also been reported in patients from Korea [29].

The human CYP27B1 enzyme is encoded by a single gene of nine exons and eight introns that is 5 kb in length [30]. The ferredoxin-binding domain is encoded by sequences contained in exons 6 and 7, while the heme-binding domain is contained in exon 8 [30,31].

At the time of updating of this chapter, 83 distinct CYP27B1 mutations causing VDDR1A had been reported (Table 66.2). Identified disease-causing sequence changes include missense and nonsense mutations, deletions, duplications, and splice mutations [7,14,23,29,32,34,35,38–45,47–54]. These mutations are dispersed throughout the CYP27B1 gene, affecting all exons and five introns (Table 66.2). There are a fair number of compound heterozygous mutations (different mutation on each CYP27B1 allele) in affected patients. A frequent mutated allele is the 7bp insertion (CCCACCC) in exon 8 (c.1325–1332ins7), present in several unrelated ethnic groups [23,32,34,35,41]. This mutation alters the downstream reading frame, causing a premature stop codon 16bp downstream. One patient was also reported with a 9bp insertion at the same position (c.1325\_1334ins9), again causing a frame shift and further suggesting that this area is a mutational hot spot [34].

CYP27B1 structure models based on other cytochrome P450 proteins have some credibility, such as the three-dimensional model of human CYP27B1 based on the crystal structure of the rabbit microsomal P450 enzyme, CYP2C5 [58]. This model allowed prediction of the outcome of several mutations causing VDDR1A [59]. Similarly, linear alignment of P450 enzyme sequences permits logical deductions concerning the impact of VDDR1A disease-causing mutations on CYP27B1 catalytic activity [34,60].

A number of assays have also been used to study the enzymatic activity of the missense CYP27B1 mutants, including expression of the recombinant protein in heterologous cells that express the electron carriers

adrenodoxin reductase and adrenodoxin [34], activation of vitamin D receptor–dependent gene transcription [45,49], or enzymatic activity in peripheral blood mononuclear cells [23,48]. In the few cases where missense CYP27B1 mutant proteins retained residual capacity to hydroxylate 25(OH)D on carbon 1 (assayed by expressing the mutant cDNA in heterozygous cells), the VDDR1A patients exhibited mild clinical biochemistry changes [39,43]. However, most of the mutant proteins tested did not retain enzymatic activity, a surprising finding considering that residual amounts of 1,25(OH)<sub>2</sub>D were measured in the serum of patients harboring the studied mutations [49]. Whether this reflects spurious 1 $\alpha$ -hydroxylation of 25(OH)D by other cytochrome P450 proteins when CYP27B1 is defective or detection of food-derived 1,25(OH)<sub>2</sub>D is unclear [49].

Thus, establishing genotype–phenotype correlations has been challenging in VDDR1A. An interesting approach using correlation between CYP27B1 mutations, age at presentation, height standard deviation score and calcitriol doses required for treatment has been reported [61]. Using these metrics, it was possible to establish statistically significant genotype–phenotype correlations among the three most prevalent mutations within the Turkish population. Of clinical severity (milder to more severe), the mutations were ranked as p.K182E < p.F443Pfs\*24 (the 7bp duplication) < c.195+2T > A (intron 1) [61]. It could prove useful to compare the height, age at presentation, and calcitriol dose of treatment for all mutations to determine the validity of the genotype–phenotype correlation across all cases reported.

## 5. Treatment of VDDR1A

Historically, patients with VDDR1A were treated with high doses of vitamin D (calciferol, 20,000 to 100,000 IU/day), in an attempt to overcome CYP27B1 deficiency, with a certain success [15,62]. Under such treatment, circulating levels of 25(OH)D increase sharply, with only minor changes in the levels of 1,25(OH)<sub>2</sub>D (Fig. 66.2). It is likely that massive concentrations of 25(OH)D are able to overcome its low affinity for the VDR to adequately bind to the VDR and act as an agonist to induce the response of the target organs to normalize calcium homeostasis. However, because such therapy leads to progressive accumulation of vitamin D in fat and muscle tissues, adjustment in case of overdose is difficult and slow to come into effect. Furthermore, the therapeutic doses are close to the toxic doses and place the patient at risk for nephrocalcinosis and impaired renal function. There have been reports on the use of 25(OH)D as therapeutic agent in VDDR1A [63]. The doses used are smaller than those of vitamin D

<sup>a</sup>Nucleotide numbers refer to coding sequence (CDS; NCBI consensus CDS database CCDS8954.1) and are numbered from the translation start site. Amino acid replacement mutations are indicated according to codon number. Nomenclature follows standard mutation nomenclature in molecular diagnostics [57]. Reference indicates first report.

and induce a similar response. The action of 25(OH)D is likely to be similar to that of vitamin D itself, by maintaining high serum concentrations of 25(OH)D. The low availability and high cost of such a preparation have discouraged its widespread use as a long-term therapy for VDDR1A. Treatment with the synthetic analog of 1,25(OH)<sub>2</sub>D, dihydrotachysterol, has also been used [64,65] but is currently discontinued.

Clinicians have used the monohydroxylated analog 1 $\alpha$ -hydroxyvitamin D (1 $\alpha$ OHD), which requires only liver hydroxylation at the 25 position (a step not affected by the VDDR1A mutation) to fully mimic 1,25(OH)<sub>2</sub>D [66]. The response is rapid with healing of rickets in 7–9 weeks, requiring a daily dosage of 2–5  $\mu$ g. The maintenance dose is about half the initial dose. Withdrawal induces a reappearance of symptoms within 3 weeks. Thus, long-term compliance is a more important consideration than in the case of vitamin D treatment. On a weight basis, 1 $\alpha$ (OH)D is about half as potent as 1,25(OH)<sub>2</sub>D, nullifying any possible economic advantage in favor of the monohydroxylated form. The reason for this difference in potency has not been investigated, but may be related to a difference in intestinal absorption or to a variable degree of 25-hydroxylation of 1 $\alpha$ (OH)D.

Since calcitriol (1,25(OH)<sub>2</sub>D<sub>3</sub>; Rocaltrol) became commercially available in 1973, the treatment of choice for VDDR1A patients is a long-term (lifelong) replacement therapy with calcitriol [17]. This results in rapid and complete correction of the abnormal phenotype, eliminating hypocalcemia, secondary hyperparathyroidism, and radiographic evidence of rickets. Strikingly, the myopathy disappears within days after initiation of therapy. The restoration of bone mineral

content is equally rapid, and histological evidence of healing of the bone structure has been observed [17].

Treatment with calcitriol (in capsules containing either 0.25 or 0.5  $\mu$ g) is started at a dose of 1.0  $\mu$ g per day, given in two doses of 0.5  $\mu$ g. Subsequently, the calcitriol dose is modified according to the results of biochemical analyses. The aims of the treatment are to achieve normocalcemia, to maintain PTH levels within normal limits and to avoid hypercalciuria. In our experience, the median daily calcitriol dose is 0.50  $\mu$ g per day (range: 0.2–1.0  $\mu$ g) after 3 months of treatment, 0.25  $\mu$ g after 1 year (range 0.1–1.0  $\mu$ g), and 0.5  $\mu$ g after 2 years (range 0.25–1.0  $\mu$ g) (personal data). An important component of treatment is to ensure adequate calcium intake during the bone-healing phase. Dietary sources are supplemented to ensure a daily supply of around 1 g of elemental calcium.

## 6. Evolution of VDDR1A under treatment from childhood to adulthood

### 6.1 Short-term effects of treatment with calcitriol

Replacement therapy with calcitriol results in rapid and complete correction of the abnormal phenotype, eliminating hypocalcemia, secondary hyperparathyroidism (Fig. 66.3), and radiographic evidence of rickets within 3 months (Fig. 66.4) [17].

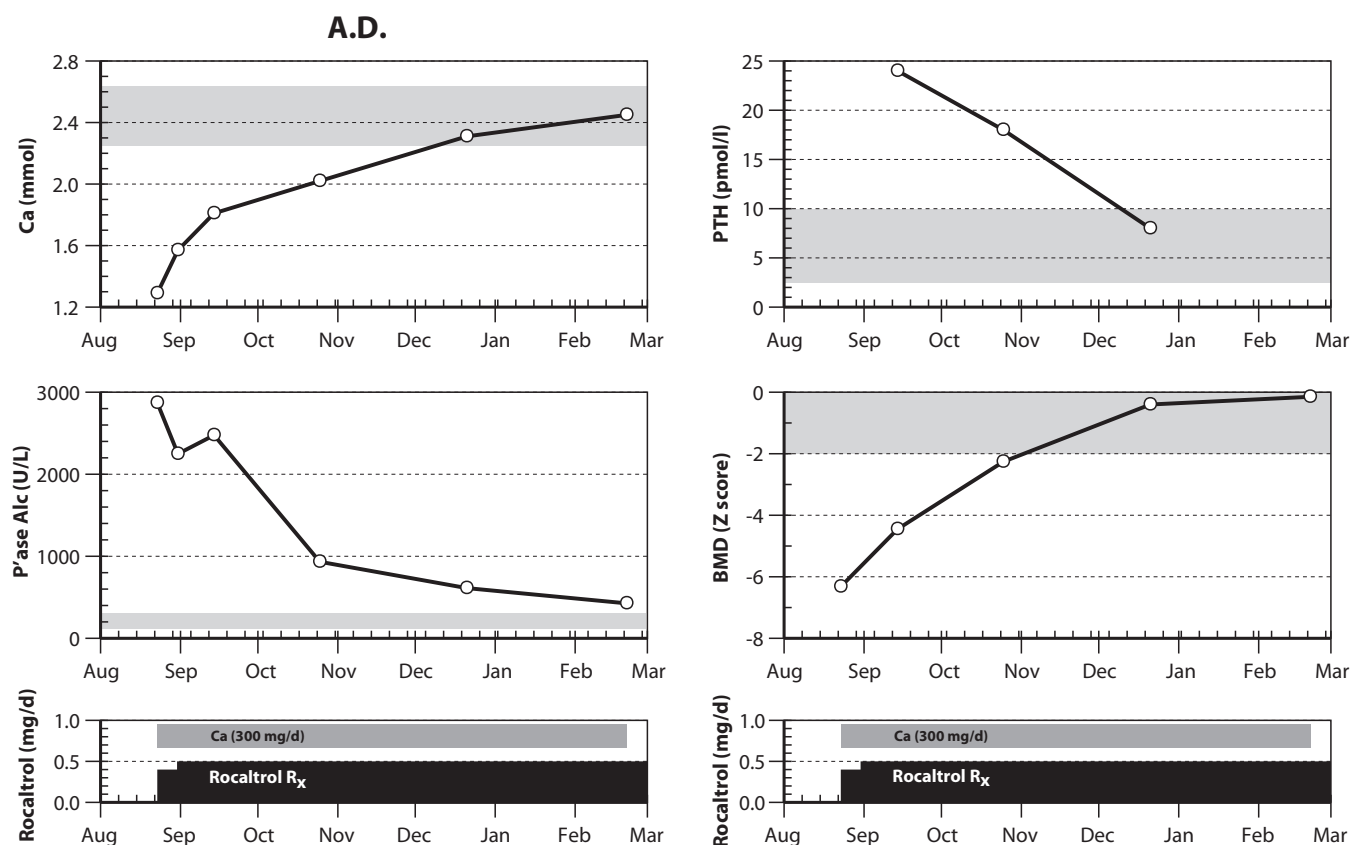

Lumbar spine areal BMD also normalizes within 3 months (Fig. 66.3) [14], as described in children and adults who are treated for vitamin D deficiency [67]. The rapidity of the increase in BMD suggests that calcitriol treatment of VDDR1A patients initially leads to the mineralization of preexisting unmineralized osteoid rather than the production of new bone matrix. Histological evidence of healing has been documented in VDDR1A patients [17] as well as in the animal model of VDDR1A [68].

The height deficit persists somewhat longer than the low areal BMD, but after 2 years of calcitriol treatment, height is also normalized (catch-up growth) and remains so until growth is completed (Fig. 66.5) [14].

Severe enamel hypoplasia is only partially corrected if treatment, as is usually the case, is started around 12–15 months of age when permanent tooth enamel has already started to develop (Fig. 66.6).

### 6.2 From childhood to adulthood

From childhood to adulthood, calcitriol doses are increased as needed to maintain serum and urinary calcium as well as PTH levels within normal limits. In our experience, in the period from 4 to 9 years of age, the

**FIGURE 66.3** Biochemical response to treatment in a patient with VDDR1A treated with calcitriol.

median daily calcitriol dose increases from 0.25 to 0.50  $\mu\text{g}$ . From 11 to 15 years of age, during the pubertal growth spurt, median calcitriol doses increase from 0.50  $\mu\text{g}$  per day to 0.75  $\mu\text{g}$  per day and remain so until adulthood [14]. The increased dose is recommended to avoid hypocalcemia and secondary hyperparathyroidism. It has been proposed that the urinary calcium to creatinine ratio, when less than 0.1 mg/mg in VDDR1A adolescent patients, is a useful biomarker to accurately evaluate calcium depletion and secondary hyperparathyroidism [69].

### 6.3 Adult patients with VDDR1A

Adult height is significantly associated with the age at which calcitriol treatment was started (Fig. 66.7) [14].

The height of adult patients who receive calcitriol before the pubertal growth spurt is normal, whereas patients who receive calcitriol only after the pubertal growth spurt are significantly shorter (Table 66.3). Lumbar spine areal BMD is normal in all adult patients whatever the treatment history. With regard to serum levels of vitamin D metabolites under calcitriol treatment, 25(OH)D levels and 1,25(OH)<sub>2</sub>D are normal in most patients.

Hypercalciuria is not infrequent during treatment with calcitriol, and changes in urinary calcium excretion are also used to adjust the daily calcitriol dose. High levels of calcium excretion may lead to calcium deposition in tissues especially in cornea and kidneys. In our treatment protocol, renal ultrasound and slit-lamp examinations of the cornea are performed every 2 years to assess for the presence of nephrocalcinosis and corneal calcium deposits. This screening for potential adverse events of hypercalcemia revealed that one patient (4% of the study population of 25) had mild corneal calcium deposits and four patients (16%) had mild nephrocalcinosis on renal ultrasound albeit with no alteration of renal function. None of our 47 patients treated with calcitriol for up to 40 years has evidence of reduced renal function (based on annual creatinine clearance evaluation). Kidney stones have never been observed (personal communication).

### 6.4 Pregnancies in women with VDDR1A

Female mice that are deficient for *Cyp27b1* (and that do not receive calcitriol) have uterine hypoplasia, absent corpora lutea, and thus are infertile [21]. This defect is at least partly due to hypocalcemia. Moreover, the

*CYP27B1* gene is expressed in human endometrial stromal cells independent of the cycle phase but with a significant increase in early pregnant decidua, suggesting a potential role of local production of  $1,25(\text{OH})_2\text{D}$  in pregnancy establishment or maintenance [70,71]. The study of decidual tissues from two *VDDR1A* patients showed

that it did not have the capacity to produce  $1,25(\text{OH})_2\text{D}$ , indicating that decidua is a target for the *VDDR1A* mutation [72]. However, the physiological importance of this defect is unclear.

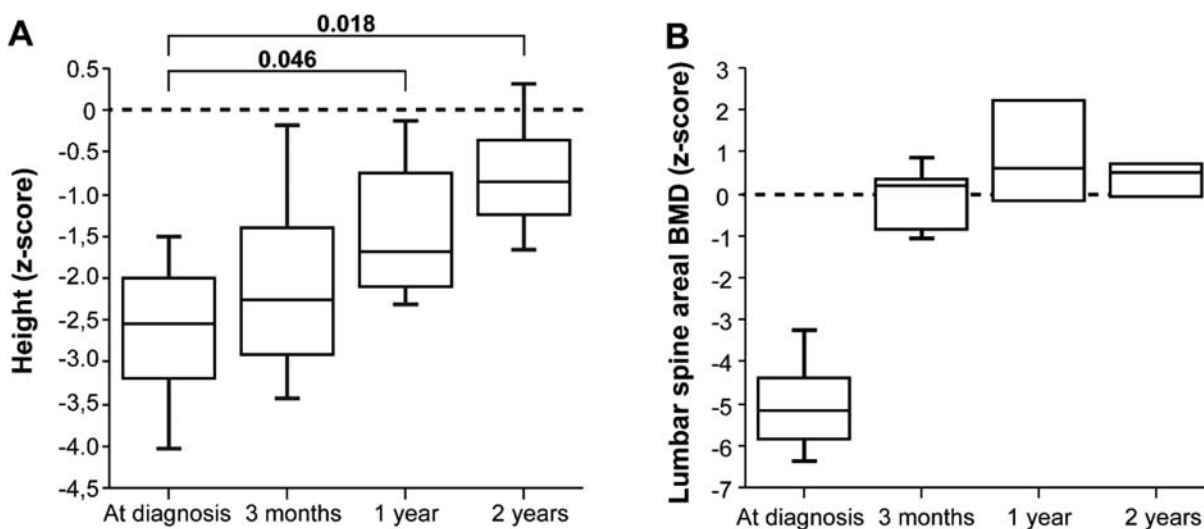

In our experience, pubertal development seemed to be normal in treated *VDDR1A* children. In our cohort, 9 of 13 women with *VDDR1A* who were above 20 years of age have had 19 documented pregnancies [14]. It therefore appears that local production of  $1,25(\text{OH})_2\text{D}$  in female reproductive organs is not critical for fertility, as systemic supplementation with calcitriol and normalization of serum calcium was sufficient to achieve fertility. During normal pregnancy,  $1,25(\text{OH})_2\text{D}$  circulating levels steadily increase to about twice the control values. This adaptation to the specific needs of pregnancy can be mimicked in pregnant women with *VDDR1A* by increasing the daily calcitriol dose during

**FIGURE 66.4** Radiographs of the right wrist (*upper panel*) and knee (*lower panel*) of a patient with *VDDR1A*, before treatment (*left panel*) and after only 3 weeks of treatment (*right panel*); healing of rickets is well underway.

**FIGURE 66.6** Permanent incisors of a 9-year-old patient with *VDDR1A* in whom calcitriol treatment was initiated at age 14 months. The part of the enamel that was formed before treatment remains hypoplastic. Subsequent to treatment, normal enamel was produced.

**FIGURE 66.5** Evolution of height (in 12 patients) and areal BMD of the lumbar spine (in five patients) during the first 2 years of treatment with calcitriol in young children with *VDDR1A*. From Ref. [14] with permission.

**FIGURE 66.7** Final height according to age of onset of calcitriol treatment in adult patients with VDDR1A. Group 1, exclusively treated with calcitriol. Group 2, initially treated with high doses of vitamin D but started calcitriol before the pubertal growth spurt. Group 3, initially treated with high doses of vitamin D but started calcitriol after the pubertal growth spurt. From Ref. [14] with permission.

the second half of pregnancy. During pregnancy, doses of calcitriol are adjusted according to the results of biochemical analyses (obtained every 4 weeks) to maintain serum calcium levels within normal limits. After delivery, calcitriol treatment is returned to prepregnancy doses. All pregnancies were without complications. In particular, there was no case of intrauterine growth retardation, and all newborns were normocalcemic at birth.

## 7. Conclusion

Vitamin D hydroxylation-deficient rickets, type 1A (VDDR1A) is a rare autosomal recessive disorder caused by mutations in the gene encoding  $1\alpha$ -OHase (CYP27B1), leading to an inability to synthesize  $1,25(\text{OH})_2\text{D}$ . This disease was the first described inborn error of vitamin D metabolism and has contributed in a major way to our understanding of vitamin D biology. The absence of any other overt phenotype besides symptoms related to hypocalcemia supports the widely held view that the major physiological role of the

Group 3: initially treated with high doses of vitamin D; started calcitriol after the pubertal growth spurt.

1,25(OH)<sub>2</sub>D hormone is to maintain mineral homeostasis.

The main site for the 1-hydroxylation of 25(OH)D is the proximal tubule of the renal cortex [73]. It is well known, however, that *CYP27B1* is expressed in extrarenal tissues such as osteoblasts [74,75], chondrocytes [76–78], keratinocytes [7], and cells of the lymphohematopoietic system [79,80] (see Chapter 9). The identification of these extrarenal sites of expression of *CYP27B1* has led investigators to hypothesize that local production of 1,25(OH)<sub>2</sub>D could play an important intracrine, autocrine, or paracrine role in the differentiation or function of the cells expressing *CYP27B1*. For example, activation of Toll-like receptors in human macrophages, a component of innate immune responses, leads to upregulation of the expression of the *VDR* and *CYP27B1*. This provokes the intracrine vitamin D–dependent induction of the antimicrobial peptide cathelicidin and increases the microbicidal activity of the macrophages [79] (see Chapter 94). These results demonstrate the physiological relevance of extrarenal *CYP27B1* expression in vitamin D–mediated innate immunity.

Molecular genetic studies have also revealed direct, but nonessential, roles for 1,25(OH)<sub>2</sub>D-mediated signaling in growth plate chondrocytes. Taken together, the results from genetic manipulation of the expression of *Cyp27b1* [81] or the *VDR* [82] in chondrocytes show a direct role for locally synthesized 1,25(OH)<sub>2</sub>D<sub>3</sub>, acting through the *VDR*, in vascular invasion and osteoclastogenesis during endochondral bone development, causing a transient increase in bone volume at the primary spongiosa [81,82].

1 $\alpha$ -OHase is expressed by both osteoblasts and osteocytes. Experiments using osteoblastic cell lines suggest that intracrine/paracrine production of 1,25(OH)<sub>2</sub>D by osteoblasts enhances their differentiation and bone mineral deposition [83–85]. Mice deficient for *Cyp27b1* specifically in osteoblasts are normocalcemic and normophosphatemic and show normal levels of circulating 1,25(OH)<sub>2</sub>D. However, conditional osteoblastic deletion of *Cyp27b1* decreased steady-state serum level of fibroblast growth factor 23 (FGF23), and local synthesis of 1,25(OH)<sub>2</sub>D in osteoblasts appears particularly important for FGF23 expression in kidney disease [86]. When the *Cyp27b1* gene was specifically inactivated in osteocytes in a model of chronic kidney disease, soft-tissue ectopic calcification was significantly increased [87], suggesting that enhanced osteocytic 1,25(OH)<sub>2</sub>D production acts as a protective mechanism against pathological soft-tissue mineralization in uremia.

1 $\alpha$ -OHase is present in many tissues in normal individuals but not expressed in the tissues of VDDR1A patients that were tested (skin, decidua, peripheral blood mononuclear cells) [7,23,72]. It is important to point

out that replacement therapy with calcitriol in VDDR1A patients leads to rapid and long-term rescue of the abnormal phenotype. Treated subjects are in general good health, fertile, and free of immunological problems. Thus, normalization of the systemic concentration of 1,25(OH)<sub>2</sub>D is necessary and sufficient to nullify the effects of the *CYP27B1* mutations. It ensures that despite all the interesting observations pointing to possible important autocrine/paracrine roles of 1,25(OH)<sub>2</sub>D in various tissues, their importance in human physiology remains to be established.

## 8. Summary points

- VDDR1A (OMIM 264700): Vitamin D hydroxylation—deficient rickets, type 1A now designates mutations in the gene encoding the 1 $\alpha$ -OHase (*CYP27B1*) and replaces previous nomenclature for the disease (PDDR, VDD, VDDR-1, or 1 $\alpha$ -OHase deficiency).
- VDDR1A is inherited as a simple autosomal recessive trait; heterozygotes are not affected.
- Generally rare, VDDR1A may be more common in genetically isolated populations as a result of founder effects.
- The treatment of choice is lifelong replacement therapy with 1,25(OH)<sub>2</sub>D<sub>3</sub>.

# The role of genetic variation in CYP2R1, the principal vitamin D 25-hydroxylase, and CYP3A4 in vitamin D homeostasis

*Jeffrey D. Roizen and Michael A. Levine*

The Children's Hospital of Philadelphia, The University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States

## OBJECTIVES

- Review the data supporting the role of CYP2R1 as the principal vitamin D 25-hydroxylase.
- Discuss the identification of *CYP2R1* as the cause for VDDR-1B.
- Discuss the effect of a rare gain-of-function mutation in CYP3A4 to cause VDDR-3.
- Review work analyzing in vitro activity effects and predicted structural effects of mutations on CYP2R1.
- Review evidence supporting the model that regulation of CYP2R1 contributes to trends in 25(OH)D observed in aging, asthma, and obesity.

## 1. Introduction

Normal vitamin D homeostasis is necessary for optimal bone and mineral metabolism and may also play an important role in modulating neurologic, immune, and cardiovascular function. For most humans, the principle source of parent vitamin D is sunlight-induced production of cholecalciferol (vitamin D<sub>3</sub>) by the skin. Ultraviolet irradiation (wavelengths between 290 and 315 nm) of keratinocytes of the stratum basale and stratum spinosum layers of the epidermis leads to

conversion of 7-dehydrocholesterol to previtamin D<sub>3</sub>, which thermally isomerizes to form vitamin D<sub>3</sub>. Vitamin D<sub>3</sub> is subsequently transported into the circulation via vitamin D-binding protein (DBP). With excessive UVB exposure, previtamin D<sub>3</sub> can also isomerize to form the inactive photoproducts tachysterol or lumisterol, which do not enter the circulation and apparently represent alternative products that prevent vitamin D toxicity. Vitamin D can also be obtained through the diet as either cholecalciferol or ergocalciferol (vitamin D<sub>2</sub>) [1]. The parent calciferols are biologically inactive, and they must undergo two hydroxylations to become fully active [2]. The first hydroxylation is performed principally in the liver by the enzyme CYP2R1, which generates 25-hydroxyvitamin D (calcidiol; 25(OH)D) [3]. A second hydroxylation is required to produce calcitriol (1,25(OH)<sub>2</sub>D), the fully active form of vitamin D. This transformation occurs principally in renal proximal tubule cells, where substrate 25(OH)D undergoes 1 $\alpha$  hydroxylation by CYP27B1 in a tightly regulated reaction that is stimulated by parathyroid hormone (PTH) and inhibited by the phosphatonin fibroblast growth factor 23 [4]. Calcitriol is degraded to inactive forms primarily by CYP24A1, but it can also be metabolized to inactive forms by CYP3A4 [5]. Although calcitriol is the hormonally active form of vitamin D, 25(OH)D is considered the most useful indicator of vitamin D status as it is the most abundant circulating form of vitamin D [6].

Vitamin D deficiency (a serum concentration of 25(OH)D less than 20 ng/mL or 50 nmol/L) and

insufficiency (a serum concentration of 25(OH)D less than 30 ng/mL or 75 nmol/L) are common conditions throughout the world, and they occur even in countries near the equator where sunlight exposure and UVB irradiation are abundant year round. One mechanism to explain lower circulating levels of 25(OH)D among people living in these regions of the world is decreased cutaneous synthesis of vitamin D<sub>3</sub> because of darker skin pigment and/or more conservative styles of dress. However, there is also emerging evidence to suggest that genetic variations in *CYP2R1* may also play an important role in pathogenesis of vitamin D insufficiency in these (and other) populations [7].

## 2. CYP2R1 is the principal human vitamin D 25-hydroxylase

The primary site of 25(OH)D production from parent vitamin D is the liver [8]. Within the liver, 25-hydroxylase activity has been identified *ex vivo* in both microsome-enriched fractions and mitochondrial fractions [9]. At least six hepatic P450 enzymes possess vitamin D 25-hydroxylase activity *in vitro* (Table 67.1): rat CYP2C11, porcine CYP2D25, rat CYP2J3, CYP27A1, CYP3A4, and CYP2R1 [10–18]. With the exception of CYP3A4, which is located in the mitochondria, all of these enzymes are associated with the microsomes. The human functional homolog of rat CYP2C11, CYP2C9, is expressed at lesser abundance in the human liver relative to CYP2C11 expression in the rat liver, and it is therefore unlikely to be responsible for significant 25-hydroxylation in humans. Similarly, the functional human ortholog of porcine CYP2D25, CYP2D6, is significantly decreased in abundance relative to CYP2D25 expression in the pig liver, and it has no detectable 25-hydroxylase activity *in vitro*. Additionally, human CYP2J2 has tenfold less activity than its rat ortholog, CYP2J3, making it unlikely to represent a significant source of 25-hydroxylation in humans.

In humans, CYP3A4 and CYP27A1 can also function as vitamin D 25-hydroxylases, but each appears to have a different primary role. CYP3A4 is expressed in the intestine and the liver, and it is the predominant hepatic P450 enzyme responsible for oxidative metabolism of a wide variety of small molecules and xenobiotics, including an estimated 60% of all clinically used drugs. CYP27A1 can 25-hydroxylate vitamin D, but it lacks specificity, and it also hydroxylates the C-26 and C-27 positions. Moreover, vitamin D metabolism and 25(OH)D levels are normal or elevated in humans [19] and mice [20] that lack functional CYP27A1, and mutations in CYP27A1 are associated with cerebrotendinous xanthomatosis [21].

By contrast, genetic studies in knockout mice in which *Cyp2r1* has been ablated [20,22], and humans with spontaneous mutations of *CYP2R1* [3,23] provide compelling evidence that CYP2R1 is the principal 25-hydroxylase for vitamin D metabolism, although it is unclear what proportion of 25-hydroxylase activity is because of CYP2R1 in mammals [20].

The *CYP2R1* gene (OMIM: 608713) is located on human chromosome 11p15.2 and contains five exons that encode a 501-amino-acid protein with a molecular mass of 57,359 Da. *CYP2R1* has homologs in all mammalian genomes that have been sequenced, and its amino acid sequence is 80% conserved across these species. In the mouse and the rat, there appear to be two predominant splice variants, but the full-length transcript is significantly more abundant than the shorter forms. The functional significance of these variants as well as the relative translation efficiency and enzymatic activity of the CYP2R1 proteins produced from these smaller transcripts has not been characterized.

CYP2R1 localizes to the microsomal membranes and has been proposed to homodimerize during gel filtration based on its apparent migration size (120 kDa) [24], though it is not clear if this homodimer exists *in vivo*. CYP2R1 coordinates a heme cofactor, and for catalytic activity, it accepts electrons from the NADPH-cytochrome P450 oxoreductase protein. Similar to other CYP-P450 enzymes, the crystal structure of CYP2R1 has a fold consisting of  $\alpha$ -helices (A–L) with  $\beta$ -sheets mostly on one side of the molecule and with the heme buried deep inside the protein (Figs. 67.1A and 67.2—heme in red [stick representation]). The core of the protein is formed by alpha helices (E, I, J, K, and L). In CYP2R1, the F–G loop contains two small helices F' and G'; this latter helix (G') is highly hydrophobic, and for another similar CYP-P450 enzyme, CYP2C9, it has been hypothesized to be associated with the endoplasmic reticular membrane. The crystal structure identifies residues (highlighted in green in Fig. 67.1A) from four helices and four loops that form the vitamin D-binding pocket (the B' helix: Leu114, Phe115, Met118, from the B–C loop: Leu125, Asn126, from the F-helix: Phe214, Asn217, Ala221, from the G helix: Ala250, Val253, Tyr254, from the I helix: Phe302, Glu306, Ala310, Thr314; from the loop between helix K and  $\beta$ -sheet 1: Val375, Ile379, and from the loop between C-terminal  $\beta$ -sheet 4: Met487, Thr488). Heme coordination relies on hydrogen bonding between the seven residues (highlighted in orange in Fig. 67.1A) orange Trp133, Arg137, Arg446, Arg109, His381, and Ser442).

Emerging understanding of CYP2R1 has stimulated great interest in this enzyme for at least three important reasons. First, CYP2R1 is highly conserved across all examined mammalian species, which implies an

**TABLE 67.1** Enzymes that have vitamin D 25-hydroxylase activity in vitro.

Enzyme (reference)	Human functional homolog	Highly expressed organs	Primary subcellular location	Preferred substrate	OMIM	Enzyme commission number (EC) for human enzyme)	Notes
Rat CYP2C11 [10]	CYP2C9	Liver	Microsomes	D3	601130	1.14.13.48	Human variants linked to poor warfarin metabolism
Porcine CYP2D25 [11]	CYP2D6	Liver	Microsomes	D2/D3	124030	1.14.14.1	Most polymorphic human CYP; human variants linked to codeine sensitivity
Rat CYP2J3 [12]	CYP2J2	Liver	Microsomes	D2 > D3	N/A	1.14.14.1	Human 25-hydroxylase activity is 10-fold less than rat functional homolog
Human CYP3A4 [15]	—	Liver, intestine, CNS, thyroid	Microsomes	D2	124010	1.14.13.97	Most abundant human CYP.
Human CYP27A1 [13]	—	Liver, lung, monocyte lineage	Mitochondria	D3	606530	1.14.13.15	Mouse knockout leads to increased serum 25(OH)D; human null variants cause cerebrotendinous xanthomatosis

**FIGURE 67.1** Overall structure of human CYP2R1. Distal view of CYP2R1 structure with  $\alpha$ -helices in light blue and  $\beta$ -strands in light pink. (A) All helices are labeled. The heme is in red (stick representation). Vitamin D3 is yellow. Residues believed to be important in the vitamin D-binding site are highlighted in green (residues from the B' helix: Leu114, Phe115, Met118, from the B-C loop: Leu125, Asn126, from the F-helix: Phe214, Asn217, Ala221, from the G helix: Ala250, Val253, Tyr254, from the I helix: Phe302, Glu306, Ala310, Thr314; from the loop between helix K and  $\beta$ -sheet 1: Val375, Ile379, and from the loop between C-terminal  $\beta$ -sheet 4: Met487, Thr488). Residues believed to be important in heme coordination are in orange (Trp133, Arg137, Arg446, Arg109, His381 and Ser442). (B) Discrete mutants clinically described (p.G42\_L46delinsR, p.L99P, and p.K242 N) are labeled with those residues visible in red (stick representation).

**FIGURE 67.2** Response of normal and mutant CYP2R1 enzymes to increasing concentrations of 1 $\alpha$ -hydroxyvitamin D3. *GAL4*, galactose 4; *UAS*, upstream activator sequence; *VDR*, vitamin D receptor. The expression plasmids were introduced into HEK293 cells with DNAs constituting the *VDR-GAL4/GAL4-UAS-luciferase* 1-hybrid reporter gene system. Relative activity is expressed as the ratio of induced firefly luciferase to control (constitutive) Renilla luciferase. Points on the graphs represent means of triplicate values established at each concentration of secosteroid.

important biological role. Investigation of CYP2R1 is thus broadly significant and clinically relevant especially given the fundamental significance of P450 enzymes to metabolism of hormones and drugs. Second, expression of CYP2R1 in nonhepatic tissues challenges previously held notions of vitamin D metabolism. Although CYP2R1 is highly expressed in the liver, recent analyses have shown that this enzyme is also expressed at significant levels in the testis [25–29], which raises important questions about the role of locally produced

metabolites of vitamin D in the testis, and the contribution of the testis to systemic vitamin D metabolism. For example, testicular CYP2R1 is reduced in patients with idiopathic testicular failure and correlates with lower circulating levels of 25(OH)D and increased serum PTH [25]. And perhaps not unexpectedly, vitamin D has reciprocal effects on testicular function and fertility: irrespective of cause, reduced circulating levels of 25(OH)D are associated with decreased sperm quality [30,31], and sperm motility is stimulated by calcitriol in vitro [32]. The production of CYP2R1 transcripts by spermatogonia supports the possibility that high local concentrations of 25(OH)D, or calcitriol, may be critical for normal maturation of spermatogonia. Vitamin D receptor (VDR) KO mice have altered expression of estrogen receptor subtypes in spermatogonia [33] as well as elevated gonadotropin concentrations [34]. Moreover, low serum levels of 25(OH)D in patients with Klinefelter syndrome [35] may reflect another consequence of testicular dysfunction, and it has been proposed by some that reduced serum levels of 25(OH)D may be as or more important than low circulating levels of testosterone as an explanation for low bone density and osteoporosis in these patients [36].

Third, and as described in greater detail in the following, genome-wide association studies (GWAS) have identified variants in or near the *CYP2R1* locus, which are associated with serum concentrations of 25(OH)D, providing evidence that genetic factors as well as environment and diet influence production of 25(OH)D. Moreover, Mendelian randomization studies implicate these same variants as predisposing to complications of obesity, multiple sclerosis, and overall

mortality. Therefore, understanding how variants effect CYP2R1 activity and predispose to disease may guide development of novel approaches for prevention and/or treatment of these disorders.

### 3. CYP2R1 and vitamin D-dependent rickets

Mutations in *CYP2R1* that reduce expression or function of the CYP2R1 enzyme have been associated with rickets and low circulating levels of 25(OH)D, with reduced responsiveness to vitamin D supplementation [3,23,37–40]. This condition is now considered a unique form of vitamin D-dependent rickets (VDDR) termed type VDDR-1B (OMIM #600081). Subjects described in these reports require increased vitamin D supplementation or calcium supplementation to treat their clinical rickets (Table 67.2) and show decreased responses to vitamin D supplementation that are gene dose-dependent (Table 67.3).

The initial description of what has come to be known as VDDR-1B was published in 1994 [37]. Two brothers of Nigerian origin who were living in Baltimore presented with rickets and very low serum concentrations of 25(OH)D that did not respond appropriately to therapeutic doses of vitamin D. It was not until a decade later that the genetic basis for this unusual form of vitamin D resistance was identified as homozygous missense mutations (p.L99P) in *CYP2R1* [3]. Functional studies revealed that recombinant CYP2R1 enzyme carrying the p.L99P mutation had negligible 25-hydroxylase activity compared with wild-type recombinant CYP2R1 whether the substrate was vitamin D<sub>2</sub> or vitamin D<sub>3</sub>. These observations provided evidence that loss-of-function mutations in *CYP2R1* are a novel cause of VDDR and, second, that CYP2R1 is the primary vitamin D 25-hydroxylase in humans.

Subsequent work described the vitamin D pathophysiology in individuals homozygous for the p.L99P mutation but residing in Nigeria [38]. The subject had clinical rickets and very low serum 25(OH)D, despite extensive sun exposure. The subject who was homozygous for the p.L99P mutation had low calcium, low phosphorous, elevated serum 1,25(OH)D<sub>2</sub>, and also undetectable 25(OH)D. By contrast to other forms of VDDR, however, a relative who was heterozygous for the p.L99P mutation had a decreased basal 25(OH)D concentration reflecting a pathophysiologic effect of haploinsufficiency. Interestingly, this work also described greater responses to large doses of cholecalciferol relative to ergocalciferol in both homozygotes and heterozygotes for the p.L99P mutation, perhaps reflecting the possibility that this mutant, or other enzymes with 25-hydroxylase activity, can hydroxylate cholecalciferol better than ergocalciferol.

A later report of VDDR-1B described compound heterozygous mutations in an affected member of a family of Middle Eastern descent [39]. One of these mutations is an insertion and frameshift mutant (c.768\_769insT (p.L257SfsX6)), and the other is a change in the splice donor site at the end of exon two (c.367 + 1, G → A). The insertion results in a frameshift and the deletion of amino acids involved in forming the binding site for vitamin D, whereas the splice site mutation removes a splice site that is present in all of the reported splice variants for *CYP2R1* mRNA. Both of these changes are predicted to result in nonfunctional proteins; however, no molecular or functional studies performed to confirm these predictions have been published. Absent such studies, it is not clear whether the loss of the donor site leads to production of a protein that includes sequences encoded by retained intronic DNA, a protein missing amino acids in a skipped exon, or no protein production at all from this allele. The female index case described in this paper was able to increase her serum 25(OH)D concentration into the normal range with high-dose vitamin D supplementation consisting of 5000 IU cholecalciferol per day, which might indicate a partial deficiency of CYP2R1 rather than an absolute deficiency, or as previously speculated, the contribution of alternative 25-hydroxylase enzymes. By contrast, an affected male sibling was not able to increase his 25(OH)D into the normal range despite supplementation with 10,000 IU of cholecalciferol per day, which was attributed to poor compliance. An alternative explanation for the discrepant 25(OH)D response to vitamin D of the two affected siblings is unbalanced transcription from the two alleles, assuming one mutation is more destructive than the other, or possibly sex-dependent dimorphism for CYP2R1 activity, or for another 25-hydroxylase. No studies were performed in the heterozygous relatives.

More recent work [23] described in greater detail the pathophysiology of subjects from Nigeria with VDDR-1B who were homozygous for the p.L99P mutation from two families, as well several of as their heterozygous relatives. In addition, a subject heterozygous for a novel missense mutation, p.K242N, was also described. As in the initial report, basal serum levels of 25(OH)D were lower in both homozygotes and heterozygotes. In addition, subjects who were homozygous for the p.L99P mutation showed negligible 25(OH)D responses to oral administration of vitamin D<sub>2</sub> or vitamin D<sub>3</sub>, whereas subjects who were heterozygotes for the p.L99P and p.K242N mutation had greater responses that were still subnormal consistent with a pathophysiologic effect of haploinsufficiency.

Finally, the most recent report characterizing individuals with VDDR-1B describes two unrelated families in France [40]. One family had several individuals who

**TABLE 67.2** Biochemical and clinical features of subjects with *CYP2R1* mutations.

Publication	Subjects	Mutation	Serum calcium (2.18–2.58 mmol/L)	Serum phosphorus (adults: 0.8 –1.5 mmol/L; children: 1.3 –2.3 mmol/L)	Serum alk phos (adults: 38–126 U/ L; children: Age and gender dependent, generally 90 –500 U/L)	Serum 25(OH)D (>50 nmol/L)	Serum 1,25(OH)2D (58–156 pmol/ L)	Serum PTH (11 –54 pg/mL; 1.2 –5.8 pmol/L)	Clinical response to supplementation

were homozygous for the p.L99P mutation and who were the result of a consanguineous union. A second family included an individual who was homozygous for a novel p.G42\_L46delinsR mutation. Individuals from this first family were reported to normalize their biochemical and bone defects with calcidiol treatment, whereas the individual in the second family was reported to normalize his biochemical and bone defects with alfacalcidol ( $1\alpha(\text{OH})\text{D}$ ) [40].

In addition to these reports, an additional publication describes a family with a VDDR-1B phenotype that appears to be inherited in an autosomal dominant fashion [41]. However, the authors of this publication were unable to identify any exomic or splice site mutations in the *CYP2R1* alleles.

To date, five mutations in the *CYP2R1* gene have been identified in individuals with VDDR-1B. By contrast, publicly available databases of human exome sequences indicate that there are many *CYP2R1* variants in the normal human population, including nonsynonymous nucleotide substitutions that lead to replacement of amino acids in the *CYP2R1* protein. In sum, the combined publicly available databases that include the exomic sequence for *CYP2R1* for more than 10,000 individuals (the National Heart, Lung, and Blood Institute (NHLBI) exome variant project (<http://evs.gs.washington.edu>), the ENSEMBLE sequencing project ([http://useast.ensembl.org/Homo\\_sapiens/Info/Index](http://useast.ensembl.org/Homo_sapiens/Info/Index)), and the 1000 genomes project (<http://www.1000genomes.org/>)) describe more than 200 different nonsynonymous variants (Table 67.4 includes nonsynonymous variants occurring more than 1/10,000 or clinically described nonsynonymous variants). The five mutations reported in the publications above (noted by a + in column 3, Table 67.4) represent a small proportion of the known genetic variability of *CYP2R1* (13% of the reported nonsynonymous variation); however, none of the reported nonsynonymous variants occurs in even 1% of the normal population overall, and the totality of the variants described in Table 67.4 occurs in 0.9% of all alleles or less than 2% of the population. We examined activity of the most common variants [7], and we have reported the Polyphen2 [42] and SIFT [43] predictions for each of these variants (columns 6 and 8 of Table 67.4). Of the variants that we found to alter or predict to significantly alter *CYP2R1* activity by both Polyphen2 and SIFT only p.L99P occurs as frequently as 1 in 1000 sequenced alleles. Interestingly, this mutant has a prevalence that varies significantly across populations. This mutant allele is most prevalent in areas with high UV light exposure (with a prevalence in 1000 genomes data approaching 10% in some populations indigenous to sub-Saharan Africa). We found that

this pattern was echoed in less functional variants of the vitamin D–binding protein [43]. The low rate of nonfunctional alleles overall suggests that there is significant evolutionary pressure to maintain normal *CYP2R1* activity in areas of low UV exposure. However, the increased rate of nonfunctional alleles for *CYP2R1* as well as the vitamin D–binding protein in areas of high-UV exposure suggests that these mutants may protect against vitamin D excess in this context.

The clinical phenotype of VDDR1B (summarized in Table 67.2) reveals several interesting features. First, the severity of vitamin D deficiency and clinical disease in subjects with *CYP2R1* mutations appears to lessen with age. The metabolic improvement with age may reflect the emergence of vitamin D-independent mechanism(s) for intestinal absorption of calcium that have been associated with postpubertal concentrations of reproductive hormones [44]. Alternatively, there may be a greater role for alternative 25-hydroxylases with age. And second, several options for management of VDDR-1B are available. The most common approach is to treat VDDR-1B patients with pharmacologic doses of ergocalciferol or cholecalciferol and/or calcium. An alternative approach is to bypass the defect in 25-hydroxylation by using calcitriol or recently available calcidiol. Remarkably, Molin et al. successfully treated one of their patients with alfacalcidol ( $1\alpha(\text{OH})\text{D}$ ) [40]. This approach may be effective specifically in the context of the mutation they describe (homozygous for p.G42\_L46delinsR). Another possibility is that  $1\alpha(\text{OH})\text{D}$  is a better substrate than ergocalciferol or cholecalciferol for alternate 25-hydroxylases; *CYP3A4*, for instance, has increased 25-hydroxylase activity for  $1\alpha(\text{OH})\text{D}$  over the calciferols [15].

#### 4. CYP3A4 and vitamin D–dependent rickets

Hereditary vitamin D–dependent rickets are disorders in which rickets arises from genetic defects impairing vitamin D activation or responsiveness to activated vitamin D. Until recently, these disorders were all due to loss-of-function mutations; VDDR-1B and mutations in *CYP2R1* were paradigmatic. By contrast to previously described vitamin D–dependent rickets, we recently identified a novel form of vitamin D–dependent rickets (VDDR-3; OMIM #619073) that occurs due to a gain of function mutation in *CYP3A4* [5]. Clinically, VDDR-3, similar to VDDR-1A and VDDR-1B, is characterized by early-onset rickets, reduced serum levels of the vitamin D metabolites 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D, and deficient responsiveness to the parent molecule. However, differing from the clinical picture in VDDR-1A and VDDR-1B, and more

similar to VDDR-2, these patients were also seemingly resistant to activated forms of vitamin D. The two index subjects require very high doses of vitamin D supplementation or calcium supplementation to treat their clinical rickets and show decreased responses to vitamin D supplementation.

CYP3A4 oxidizes 25-hydroxyvitamin D principally via hydroxylation at the 4-beta position and inactivates 1,25-dihydroxyvitamin D via hydroxylation at the 23-R position [45,46]. Although the relevance of CYP3A4 to vitamin D homeostasis is limited under physiological conditions, previous studies indicate that under special circumstances, CYP3A4 can have important effects on vitamin D metabolism. First, induction of CYP3A4 expression by anticonvulsants and many other drugs is associated with clinically significant vitamin D deficiency via accelerated inactivation of vitamin D metabolites [45,46]. Second, targeted induction of CYP3A4 by the antibiotic rifampin has been shown to provide an alternative inactivation pathway that can normalize elevated levels of vitamin D metabolites in patients with loss-of-function mutations in *CYP24A1* [47]. Finally, common polymorphisms in CYP3A4 are associated with decreased bone density, although the mechanism remains uncertain [48].

The initial description of what has come to be known as VDDR-3 describes two unrelated female subjects from nonconsanguineous families. Both subjects initially presented to medical attention prior to the age of 2 years with clinical and radiological features of rickets including bowed legs, delayed walking, poor growth, reduced serum calcium and phosphorus, and elevated serum alkaline phosphatase and parathyroid hormone. Whole-exome sequencing followed by targeted Sanger sequencing revealed that the genetic basis for this unusual form of vitamin D resistance was identified as heterozygous gain-of-function missense mutations (p.I301T) in *CYP3A4* [5]. Functional studies revealed that recombinant CYP3A4 enzyme carrying the p.I301T mutation had tenfold increased activity to inactivate 1,25(OH)D compared with wild-type recombinant CYP3A4 and twofold increased activity compared with wild-type recombinant CYP24A1. Additionally, the p.I301T mutation decreases CYP3A4 activity for the research assay substrate luciferin IPA by nearly 50%. Expression of CYP3A4 can be induced by a wide variety of compounds that bind to the steroid and xenobiotic nuclear receptor. There is evidence of a feed-forward loop whereby bile acids, which are metabolized by CYP3A4, induce CYP3A4 [5]. Thus, the decrease in non-vitamin D catalytic activity we observe in the p.I301T mutant may serve to induce the expression of this mutant CYP3A4 and further increase 1,25-dihydroxyvitamin D<sub>3</sub> degradative activity.

## 5. In vitro and in silico analyses of CYP2R1 function

Two in vitro methods have been used to characterize CYP2R1 activity; conversion of radiolabeled parent vitamin D (ergocalciferol or cholecalciferol) to 25(OH)D in lysed or cell-free extracts or cell culture-based assays in which activity of recombinant CYP2R1 proteins is determined using a two-hybrid luciferase reporter system. The former method uses thin-layer chromatography to separate parent vitamin D from 25(OH)D, and it is an adaptation of an ex vivo method that has been in use since at least the 1960s for measurement of hepatic 25-hydroxylase activity [49]. With highly sensitive mass spectroscopy and chromatographic methods that can distinguish 25(OH)D<sub>3</sub> and 25(OH)D<sub>2</sub>, it is now theoretically possible to perform this cell-free assay without the use of radioactivity. Such an assay has not yet been reported in the literature. However, the second approach employs a luciferase reporter in which expression of recombinant firefly luciferase is dependent on activation of promoter sequences that contain DNA response elements that bind either the VDR or galactose 4 (GAL4)—VDR hybrid proteins consisting of a fusion between the GAL4 DNA-binding domain and the human VDR ligand-binding domain [18]. In its current iteration, this assay has been modified to enhance sensitivity by using 1- $\alpha$ (OH)-cholecalciferol as the substrate instead of cholecalciferol and a destabilized firefly luciferase (Fig. 67.1) [3,23]. Cells transfected with CYP2R1 cDNA (sequence A in Fig. 67.1) generate 1,25(OH)2D<sub>3</sub> when incubated with 1 $\alpha$ (OH)cholecalciferol; the 1,25(OH)2D<sub>3</sub> binds to the VDR ligand-binding domain in the hybrid VDR-Gal4 protein enabling the GAL4 domain to interact with copies of the yeast Gal4 upstream activator sequence in the reporter plasmid, thereby activating transcription of destabilized firefly luciferase.

The functional characteristics of only two (p.L99P and p.K242 N) of the five CYP2R1 mutants (p.L99P, p.K242N, p.G42\_L46delinsR, c.DNA367 + 1, G  $\rightarrow$  A, c.768insT (p.L257SfsX6)) that have been identified in patients with VDDR-1B have been reported [3,23,38] (Fig. 67.2). The remaining three mutants (p.G42\_L46delinsR, c.DNA367 + 1, G  $\rightarrow$  A, c.768insT (p.L257SfsX6)) are predicted to have reduced activity because of the loss or replacement of amino acids in important functional domains that have been identified by in silico analysis of the crystal structure of the CYP2R1 protein [24].

The splice site mutation (c.DNA367 + 1) is predicted to result in replacement of more than one-third of the functional CYP2R1 protein, including residues critical for the vitamin D-binding pocket (Leu125, Asn126, Phe214, Asn217, Ala221, Ala250, Val253, Tyr254, Phe302, Glu306, Ala310, Thr314, Val375, Ile379,

Met487, and Thr488) as well as residues necessary for heme coordination (Trp133, Arg137, Arg446, His381, and Ser442). Similarly, the insertion mutant leading to a premature stop codon (p.L257SfsX6) is predicted to result in omission of nearly half of the amino acids in CYP2R1 including many of the same critical amino acids for the vitamin D-binding site and heme coordination. The effect of the short insertion mutant (p.G42\_L46delinsR) is less obvious as these amino acids are all in the A' loop, which has unclear function. In the crystal structure (Fig. 67.2B—the residues for each of the three discrete mutants, p.G42\_L46delinsR, p.L99P, and p.K242N, are identified), the sequence this loop continues from is cut off to facilitate crystallization; the transmembrane portion of the protein, residues 1–31, was replaced in the crystalized protein with the amino acid sequence MAKKT. The length of the replacement in the mutant is fairly long, and it may be necessary to allow movement on the microsomal membrane or interaction with membrane components.

The p.L99P mutation is predicted by Polyphen2 [42] and SIFT [43] to result in a misfolded protein; specifically, structure modeling found that replacement of leucine99 by proline, a helix breaker, disrupts the helix that this leucine is involved in, likely resulting in an increased degradation rate. However, when this mutant protein is overexpressed in cell culture, there is no evidence of decreased protein abundance relative to the wild-type protein [23]. In addition to the structural effect that is expected by the replacement of leucine with proline in any protein, L99 is in close proximity [24] to several residues that coordinate the heme cofactor (Fig. 67.2B) and appears to form a critical hydrogen bond with Arg445 that may be necessary for appropriate positioning or electron availability for heme coordination.

Replacement of lysine242 by asparagine is predicted by SIFT [43] to be damaging and by Polyphen2 [42] to be possibly damaging to protein structure. In addition, and similar to p.L99P that has both predicted effects on protein structure generally and predicted effects on CYP2R1 function specifically, this change is predicted to destabilize positioning of Phe240 with consequent decreased interaction of CYP2R1 with its substrate.

## 6. Associations between CYP2R1 variants and disease

There is extensive genetic variation in *CYP2R1*, and many different *CYP2R1* alleles exist within the normal population, including common single nucleotide polymorphisms (SNPs) in noncoding and coding regions that do not alter the sequence of CYP2R1 as well as rare nonsynonymous SNPs in exons that result in amino

acid replacements. GWAS have consistently linked serum concentrations of 25(OH)D to SNPs in or near the *CYP2R1* locus across ethnicities [46,50–53]. Because low 25(OH)D concentrations are implicated in a number of disease states, several groups have examined whether the SNPs associated with 25(OH)D in GWAS are also associated with specific disease states; these analyses demonstrated significant associations between *CYP2R1* SNPs associated with low serum 25(OH)D and multiple sclerosis [54], type 1 diabetes [55,56], obesity [57], asthma [58,59], and elevated serum IgE [60] (Table 67.5). However, these studies have several important limitations. First, these are association studies and thus, cannot demonstrate the direction of causality. And secondly, these studies do not correct for genetic background as a confounder. Hence, it is not possible to conclude that low serum levels of 25(OH)D represent a modifiable cause of these common diseases. Specifically, to conclude that a reduced serum level of 25(OH)D represents a risk factor that actually causes these diseases, it will be necessary to demonstrate that increasing serum levels of 25(OH)D will result in a beneficial effect. The traditional approach to prove disease causation by a deficiency is through a randomized placebo-controlled interventional trial in which the deficiency is corrected. An alternative, and more expedient approach, is to use Mendelian randomization, a methodology that utilizes variation in genes of known function to examine the causal effect of a modifiable exposure on a disease or condition. The design was first described by Katan [61] as a way to understand the relationship between low cholesterol and cancer and more fully characterized by Gray and Wheatley [62] as an alternative to intervention trials for obtaining unbiased estimates of the effects of a putative causal variable. The design includes a powerful control for elimination of reverse causation and confounding effects that can reduce the reliability of conventional epidemiological studies. When performed properly, Mendelian randomization examines both the direction of causality in described associations and the strength of that association. This technique can use genetic variation to predict the outcome for a modifiable feature in subjects who have not actually had the feature measured (e.g., serum concentration of 25(OH)D) and hence can be applied to populations for which specific outcomes are known (e.g., multiple sclerosis, asthma, hypertension, etc.). Mendelian randomization for 25(OH)D uses GWAS-derived variants in *CYP2R1* as well as *GC* (encoding DBP) and *DHCR7* (encoding 7-dehydrocholesterol reductase) to generate a 25(OH)D propensity score. This score has been found to account for ~ 10%–15% of the total variation in serum levels of 25(OH)D (i.e., approximately 25 nmol/L) and is an index of the genetic predisposition toward low serum 25(OH)D. In Mendelian randomization analyses, SNPs

**TABLE 67.5** Associations between *CYP2R1* single nucleotide polymorphisms and serum levels of 25(OH)D or specific clinical disorders.

Gene or SNP	Location	Phenotype
	(Relative to <i>CYP2R1</i> )—position on chr 11

rs2060793	(3')—14866810	Serum level of 25(OH)D [50]

SNPs, single-nucleotide polymorphisms.

that are located in the *CYP2R1* promoter, via their effect on serum levels of 25(OH)D, have confirmed that reduced serum 25(OH)D levels are likely causally associated with several adverse outcomes, including multiple sclerosis, hypertension, and overall mortality [63–65]. By contrast, Mendelian randomization with SNPs within the *CYP2R1* promoter have demonstrated reverse causality for low serum levels of 25(OH)D and pediatric asthma, suggesting instead that asthma causes low circulating concentrations of 25(OH)D [66].

An important and as yet unanswered question is whether the *CYP2R1* polymorphisms that have been associated by GWAS with serum levels of 25(OH)D actually alter expression of *CYP2R1* or are in linkage disequilibrium with the true functional polymorphisms. One approach to address this question is to determine whether the SNPs are located in sequences with DNase hypersensitivity, which are generally thought to be regulatory domains, where transcription factors bind to control gene expression. Although DNA hypersensitivity sites within the human genome have been mapped by the ENCODE project, these sites have been identified using DNA from circulating blood cells and cancer cell lines, and not from cells and tissues that normally express *CYP2R1*, such as the liver and testis, which may have different DNase hypersensitivity sites. With these limitations in mind, analysis of the available ENCODE data shows that the commonly used *CYP2R1*

polymorphisms do *not* reside in DNase hypersensitivity sites and hence are likely to be nonfunctional. Rather, these SNPs may represent “tag SNPs” that are in linkage disequilibrium with the actual DNA sequences that mediate the measured effect. If the identified SNPs are tag SNPs rather than functional SNPs, then it is likely that the associations between *CYP2R1* and circulating levels of 25(OH)D are actually more significant than what has actually been measured.

## 7. Regulation of *CYP2R1* in health and disease

Vitamin D concentrations are decreased in pathologies as diverse as asthma, obesity, diabetes, and aging. These decreases have long been thought to reflect that low vitamin D predisposes to each of these pathologies. Our work using mendelian randomization to examine direction and degree of causality in the relationship between asthma and low serum vitamin D (25(OH)D) found that low serum 25(OH)D is likely an effect of asthma rather than a cause [66]. This work raises the possibility that low 25(OH)D concentrations in other diseases are effects of the disease rather than a cause.

One mechanism that might link disease to low 25(OH)D concentrations would be decreased *CYP2R1* activity. This is a controversial possibility, as *CYP2R1*

had previously been thought to be a constitutive enzyme. Our group used mouse models of aging and obesity to examine the possibility that aging and obesity decreased *CYP2R1* abundance and activity, leading to lower 25(OH)D concentrations. We found the both aging and obesity decreased liver *CYP2R1* mRNA and 25-hydroxylase activity, leading to decreased serum 25(OH)D [67,68]. Thus, we demonstrated that regulation of *CYP2R1* in the context of disease may mediate the association between some disease states and low serum 25(OH)D concentrations.

## 8. Conclusion

Recent genetic and biochemical studies of *CYP2R1* have revealed this protein to be far more important for vitamin D homeostasis than previously imagined. Heterozygous loss-of-function mutations in the *CYP2R1* gene account for vitamin D deficiency and decreased responsiveness of 25(OH)D to vitamin D supplementation, and when homozygous, cause VDDR-1B. Therefore, unlike most genes that encode important enzymes, *CYP2R1* exhibits a gene-dose effect such that there is a haploinsufficient phenotype. Perhaps even more important than the handful of *CYP2R1* mutations that have been described, ~150 nonsynonymous variants have been reported in publicly available databases, and although these variants are uncommon in the normal populations studied, there is reason to suspect that many alter function of the *CYP2R1* protein. Finally, and perhaps of greatest clinical impact, several *CYP2R1* variants have been identified by GWAS that are associated with low-circulating 25(OH)D, and which collectively are responsible for 20%–30% of the genetic contribution to serum levels of 25(OH)D. Moreover, these variants have been used to confirm causal relationships between reduced circulating levels of 25(OH)D and several common diseases, such as obesity, asthma, and multiple sclerosis, as well as overall mortality. Understanding how these variants affect *CYP2R1* activity and lead to disease may suggest innovative approaches to improving health. Although genetic variation has been a larger focus of research, recently, we have reported three lines of evidence suggesting that in specific contexts (i.e., asthma, aging, and obesity), transcriptional regulation of *CYP2R1* has clinically significant effects on its activity and serum 25(OH)D.

By contrast to *CYP2R1*, in normal conditions, *CYP3A4* does not play a prominent role in vitamin D homeostasis. However, a rare gain-of-function mutation in *CYP3A4* has recently been found to cause VDDR-3. Additionally, induction of *CYP3A4* incidentally by anti-convulsants and many other drugs or therapeutically by rifampin increases inactivation of forms of vitamin D.

## 9. Summary points

- *CYP2R1* is the principal vitamin D 25-hydroxylase.
- Homozygosity for complete loss-of function mutations in *CYP2R1* causes VDDR-1B.
- Heterozygosity for complete loss-of function mutations in *CYP2R1* causes a vitamin D deficiency where individuals have decreased responsiveness to supplementation.
- An extremely rare gain-of-function mutation in *CYP3A4* causes VDDR-3.
- In specific contexts, inhibition or induction of transcription or activity of either *CYP2R1* and *CYP3A4* has clinically significant effects on vitamin D homeostasis (Tables 67.1–67.5).

# Hereditary 1,25-dihydroxyvitamin D resistant rickets (VDDR-2A)

Peter J. Malloy<sup>1</sup>, Dov Tiosano<sup>2</sup> and David Feldman<sup>1</sup>

<sup>1</sup>Division of Endocrinology, Gerontology, and Metabolism, Stanford University School of Medicine, Stanford, CA, United States <sup>2</sup>Ruth Rapaport Children's Hospital, Rambam Medical Center, Haifa, Israel

## OBJECTIVES

- To present the clinical picture of hereditary vitamin D resistant rickets (HVDRR) including the family setting and the role of consanguinity.
- Discuss the various mutations that cause HVDRR and how their location in the VDR provides information on the function of various segments of the VDR protein.
- Cover the various forms of treatment as they have evolved and expanded.
- Discuss the phenomenon of spontaneous improvement in the clinical picture around puberty and the hypothesis of how pubertal hormones may improve calcium absorption by a vitamin D-independent action.
- Examine the unusual finding of alopecia in some but not all cases of HVDRR and discuss current research to explain the mechanism and which mutations are associated with the problem.
- There is great interest today in the possible action of vitamin D to reduce the incidence and severity of many extra-skeletal diseases. Children with genetic defects that prevent vitamin D action from birth would be expected to suffer an increased incidence of these illnesses. We examine the limited number of cases being followed to determine whether they appear to have an increased risk of cancer, autoimmune disease, or other maladies including effects on reproduction.

## 1. Introduction

As discussed in many chapters in this book, vitamin D is the primary regulator of calcium homeostasis in the body and is particularly important in skeletal development and in bone mineralization. The hormonally active, form of vitamin D,  $1\alpha, 25$ -dihydroxyvitamin D [ $1,25(\text{OH})_2\text{D}$  or calcitriol], functions like other steroid hormones by binding with high affinity to its specific receptor, the vitamin D receptor (VDR). The VDR is a member of the steroid-thyroid-retinoid receptor gene superfamily of nuclear transcription factors that regulate the expression of specific target genes in response to hormone binding. Hereditary  $1,25(\text{OH})_2\text{D}$ -resistant rickets (HVDRR), also known as vitamin D-dependent rickets type 2A (VDDR-2A), is a rare genetic disease that is due to a generalized resistance to  $1,25(\text{OH})_2\text{D}_3$  action. HVDRR is caused by heterogeneous mutations in the VDR gene that cause loss of function of the receptor ultimately leading to complete target organ resistance to  $1,25(\text{OH})_2\text{D}$  action. In this chapter, we update our previous reviews on HVDRR [1–8], describe the clinical manifestations of the disease, and discuss the published genetic defects in the VDR underlying the molecular basis for HVDRR adding newly described mutations and current research.

Over the years several different names have been used to describe the condition caused by  $1,25(\text{OH})_2\text{D}$  resistance (when written without the  $\text{D}_2$  or  $\text{D}_3$  subscript we mean either/or both forms of vitamin D). In addition to the designation HVDRR, the disease has been referred to as vitamin D-dependent rickets type II (VDDR-II),

**TABLE 68.1** Comparison of VDDR-1's, VDDR-3 and HVDRR (VDDR-2A).

Mechanism	Synthesis defective		Receptor defective	Increased degradation
Descriptive Designation	1 $\alpha$ -hydroxylase Deficiency	25-hydroxylase Deficiency	HVDRR	Accelerated Catabolism
OMIM designation	VDDR-1A	VDDR-1B	VDDR-2A	VDDR-3
Gene mutated	CYP27B1	CYP2R1	VDR	CYP3A4
Recessive mutation	Yes	Yes	Yes	Dominant <sup>c</sup>
Appears early age	Yes	Yes	Yes	Yes
Rickets	Yes	Yes	Yes	Yes
Elevated Alk Phos	Yes	Yes	Yes	Yes
Hypocalcemia	Yes	Yes	Yes	Yes
Alopecia	No	No	Some patients <sup>a</sup>	No
PTH	Elevated	Elevated	Elevated	Elevated
25(OH)D levels	Normal or low	Low	Normal	Low
1,25(OH) <sub>2</sub> D levels	Low	Low	Elevated	Low
Response to doses of 1,25(OH) <sub>2</sub> D	Yes	Yes	No (with exceptions) <sup>b</sup>	Requires high dose <sup>d</sup>

<sup>a</sup>Alopecia is associated with mutations that affect DNA binding, VDR-RXR heterodimerization, or that truncate the VDR.

<sup>b</sup>Mutations that reduce the affinity for 1,25(OH)<sub>2</sub>D<sub>3</sub> can sometimes be overcome by treating with elevated concentrations of various vitamin D ligands.

<sup>c</sup>The missense mutations in CYP3A4 are de novo and dominant and are not inherited from the parents.

<sup>d</sup>The dose required to maintain adequate 1,25(OH)<sub>2</sub>D<sub>3</sub> is supra-physiologic that overcomes the accelerated degradation created by the mutation in CYP3A4.

pseudovitamin D deficiency rickets type II (PDDR-II), calcitriol-resistant rickets (CRR) and hypocalcemic vitamin D-resistant rickets (HVDRR). In the Online Mendelian Inheritance in Man web site (<http://www.ncbi.nlm.nih.gov/omim/>) this disease is now referred to as Vitamin Dependent Rickets-2A (VDDR2A). We prefer to use the designation "Hereditary 1,25-dihydroxyVitamin D Resistant Rickets" (HVDRR) since this disease is now known to be caused by genetic defects in the VDR that lead to resistance to the action of 1,25(OH)<sub>2</sub>D (not dependence on) and this simplified name is the term most used in previous publications [3,5–10]. However, there is a recent trend in some publications to use the VDDR terminology instead of HVDRR, so we will use both terms in Table 68.1 and intermittently in the text but mostly use HVDRR, the name that we believe more correctly defines the mechanism of the disease.

In summary, the VDDR terminology is as follows and is described more completely in Table 68.1 and discussed by Levine [11]. VDDR-1 is caused by mutations in genes encoding the enzymes that metabolize vitamin D to 25-hydroxyvitamin D (25(OH)D) and 1,25(OH)<sub>2</sub>D: CYP2R1 and CYP27B1. VDDR-2 (HVDRR is also known as VDDR-2A), is caused by mutations in genes encoding essential signal transducing proteins: VDR and heterogeneous nuclear

ribonucleoprotein (hnRNP) VDDR-2B. VDDR-3 is due to gain-of-function mutations in a gene encoding a vitamin D degrading enzyme CYP3A4.

Historically, the notion that some cases of rickets could be due to hormone resistance was put forward in 1937 by Albright et al. [12]. They described a patient with rickets and normal serum calcium levels but low phosphate levels who responded to treatment with very high doses of vitamin D. This led the authors to suggest that the cause of the condition was due to end-organ resistance to vitamin D and thus the concept of target gland hormone resistance developed. The patient they described appears to have had what is now known as X-linked hypophosphatemic rickets (XLH), described in Chapter 64. Twenty-four years later, Prader et al. [13] reported on two patients with rickets who were hypocalcemic and hypophosphatemic. These patients also responded to high doses of vitamin D and they referred to this condition as vitamin D-dependent rickets type I (VDDR-I). The cause of rickets in these individuals was eventually discovered to be due to an inborn error in the enzyme that converts vitamin D to the hormonally active form 1,25(OH)<sub>2</sub>D. It is now well established that VDDR-1A arises from mutations in the CYP27B1 gene that encodes the enzyme 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase (1 $\alpha$ -OHase) that converts 25-hydroxyvitamin D

[25(OH)D] to 1,25(OH)<sub>2</sub>D [4,14,15]. This disease is described in Chapter 66.

Defects in the first step of vitamin D activation, the conversion of vitamin D to 25(OH)D, are due to mutations in the gene responsible for the vitamin D 25-hydroxylation step (*CYP2R1*). This entity has now been designated as VDDR-IB and is discussed in Chapter 67.

A second mutation in the VDDR-2 category in addition to HVDRR is a defect seen so far as we are aware in only a single patient [16]. The defect is in heterogeneous nuclear ribonucleoprotein (hnRNP) that binds to hormone response elements and thereby can cause vitamin D resistance [16,17].

A recently described form of genetic rickets is termed VDDR-3. This disease is due to a gain of function mutation in the *CYP3A4* gene leading to accelerated degradation of vitamin D metabolites [18] (and Chapter 67). Although very few patients with *CYP3A4* mutations have been identified as yet, a similar mechanism may be important in drug-induced osteomalacia since some commonly used drugs stimulate *CYP3A4* activity leading to accelerated vitamin D metabolite degradation [19]. The VDDR terminology is added to Table 68.1 to describe and compare these diseases.

Focusing on HVDRR (VDDR-2A), in 1978, the first case reports of actual HVDRR were published by Brooks et al. [20] and Marx et al. [21]. The patient in the Brooks et al. study was both hypocalcemic and hypophosphatemic and had secondary hyperparathyroidism. Many clinical findings were similar to patients with VDDR-IA except that the patient had markedly increased serum levels of 1,25(OH)<sub>2</sub>D. Brooks et al. postulated that the rickets was due to end-organ resistance to 1,25(OH)<sub>2</sub>D and they named the syndrome vitamin D dependent rickets, type II (VDDR-II). Marx et al. reported similar findings in two children and also suggested that the disease was due to end-organ resistance to 1,25(OH)<sub>2</sub>D. Since these initial studies, although the condition is rare in the general population, there have been many reports of patients with HVDRR due to target organ resistance to 1,25(OH)<sub>2</sub>D action [1–10,22–24] especially from areas of the world where consanguinity is common, often in isolated communities. In this review, we will update the clinical features and the genetic basis underlying the disease and we attempt to include all of the published mutations up to the time of writing this chapter as well as reviewing new research findings.

## 2. Clinical features

### 2.1 Clinical and biochemical findings and distinguishing features

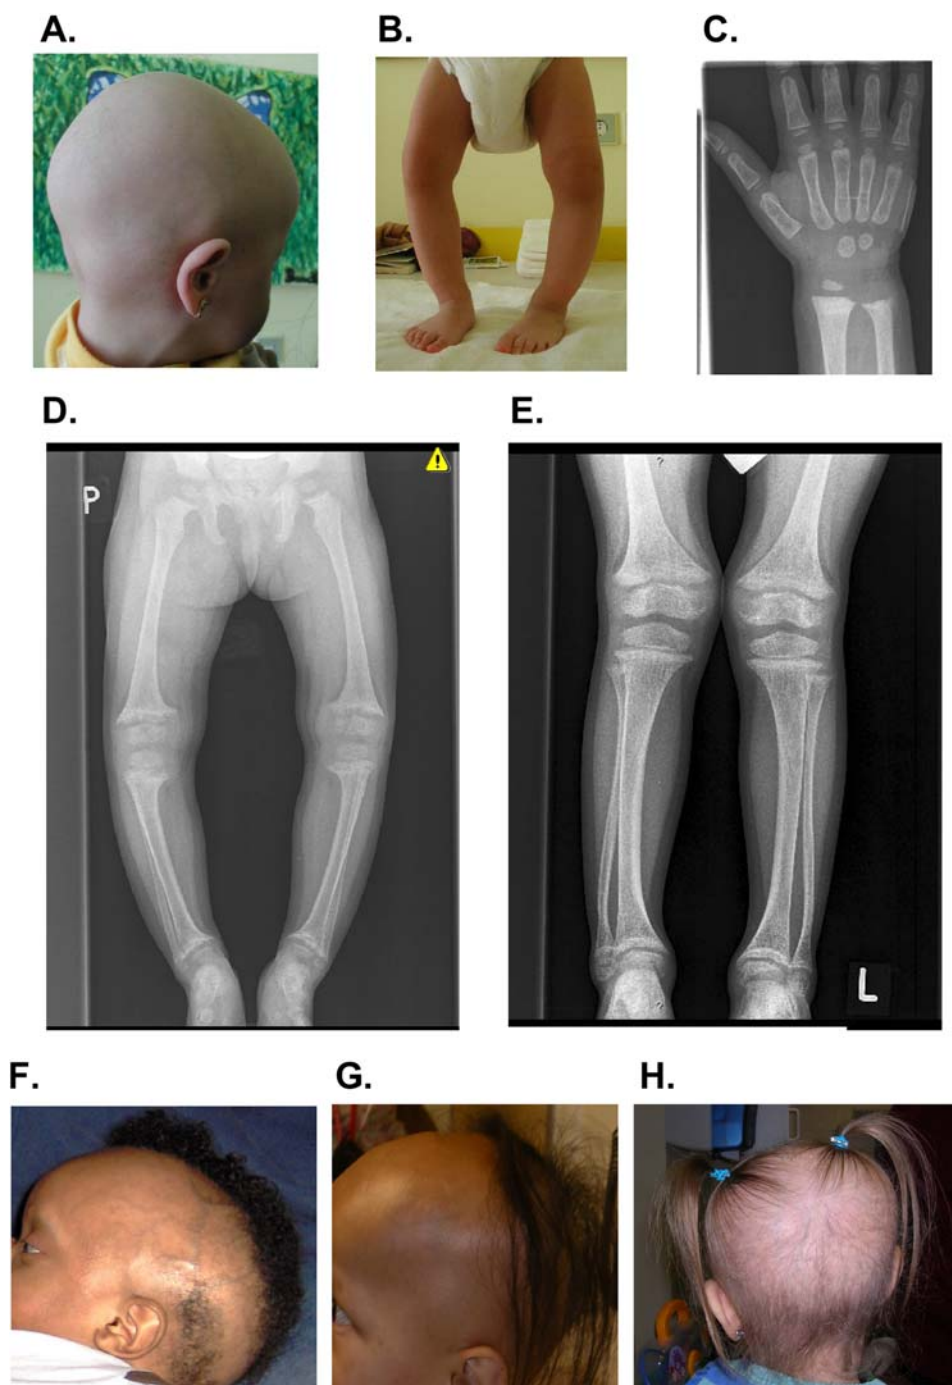

HVDRR (or VDDR-2A) is manifested by a constellation of signs and symptoms caused by generalized

resistance to 1,25(OH)<sub>2</sub>D action and by a loss of ligand-dependent and possibly ligand-independent actions of the VDR. The main features of HVDRR are severe rickets with osteomalacia, hypocalcemia, secondary hyperparathyroidism, hypophosphatemia, and elevated alkaline phosphatase. Some patients have total or partial alopecia. At birth or soon after, hair is lost and not replaced. The development of partial or complete alopecia may be the only early obvious symptom (Fig. 68.1). Alopecia, and which patients develop it, will be discussed in greater detail below in Section 8.

Calcium levels are often within normal limits soon after birth, due to adequate transfer of calcium from the mother to the fetus. Biochemically, the earliest evidence of HVDRR is often elevated serum concentration of 1,25(OH)<sub>2</sub>D. This is an inherent part of the disease due to the loss of the down-regulating effect that calcitriol has on the *CYP27B1* enzyme through VDR action, as well as the development of secondary hyperparathyroidism due to falling serum calcium levels. Hypocalcemia results in elevated parathyroid hormone (PTH) secretion and thereby increased stimulation of *CYP27B1* expression resulting in elevated production of 1,25(OH)<sub>2</sub>D [25]. During the first months of life, phosphaturia, due to secondary hyperparathyroidism, is followed by a decline in serum phosphorus. In the following months, severe rickets, with hypocalcemia and hypophosphatemia, develop rapidly. The potential role of fibroblast growth factor 23 (FGF23) or other phosphatonins involved in the phosphate abnormality, or in the elevated serum 1,25(OH)<sub>2</sub>D concentration are discussed in Chapters 19 and 64. If not treated, the growth of the child is severely attenuated and bowing of the long bones and fractures can develop. X-ray studies show classical changes in rickets (Chapter 62).

In HVDRR-affected children, signs of rickets generally appear early, usually within months of birth. The rickets is often severe and affected children suffer from bone pain, muscle weakness, and hypotonia. In the worst cases, convulsions due to the hypocalcemia have occurred. Children are usually growth retarded and they often develop severe dental caries or exhibit enamel hypoplasia of the teeth [26–30]. Some infants have died from pneumonia as a result of poor respiratory movement due to severe rickets of the chest wall [27,28,31]. In many cases, children with HVDRR have sparse body hair and some have total scalp and body alopecia including eyebrows and in some cases eyelashes (Fig. 68.1). Alopecia, and why some cases do not exhibit alopecia, will be discussed in more detail below (sub-Section 3 and Section 8).

The clinical findings in HVDRR (VDDR-2A) are shown in Table 68.1 and compared to three other genetic causes of early onset rickets due to enzymatic defects in the synthetic pathway of 1,25(OH)<sub>2</sub>D, (VDDR-1), or in the case of VDDR-3, accelerated degradation of

**FIGURE 68.1** Alopecia and rickets in children with HVDRR. HVDRR children with partial alopecia. (F) Patient F69; (G) patient F78; (H) patient F79. Panels (A–E) Reproduced from [22] with permission from the American Society for Bone and Mineral Research. Panel (F) reproduced with permission from [23]. Panels (G and H) reproduced with permission from [24].

25(OH)D and 1,25(OH)<sub>2</sub>D. In comparison with HVDRR (VDDR-2A), Table 68.1 shows the usual finding in the defects that block the 1 $\alpha$ -hydroxylase or the 25-hydroxylase, enzymes (VDDR-1) that would normally activate vitamin D to 1,25(OH)<sub>2</sub>D. Table 68.1 also includes VDDR-3 due to increased degradation of the

active vitamin D metabolites. The common clinical abnormalities in all of these diseases include low serum concentrations of calcium and phosphate and elevated serum alkaline phosphatase activity (Alk Phos). The mechanism is an inadequate synthesis of 1,25(OH)<sub>2</sub>D due to synthetic enzyme mutations (VDDR-1), or

increased degradation of the active metabolites (VDDR-3). The inability of even the elevated  $1,25(\text{OH})_2\text{D}$  to activate target genes is the mechanism in the case of VDDR-2A (HVDRR) where *VDR* gene mutations disables the VDR. All four conditions cause secondary hyperparathyroidism because of hypocalcemia. In HVDRR, the inability of the elevated  $1,25(\text{OH})_2\text{D}$  levels to activate the VDR to suppress PTH, contributes to the hyperparathyroidism. The elevated PTH level then exacerbates hypophosphatemia. Many of these clinical and biochemical findings are common to patients with the various forms of VDDR as shown in Table 68.1 and are described in detail in Chapters 66 and 67. The most obvious differences are that VDDR-2 patients have elevated  $1,25(\text{OH})_2\text{D}_3$ , may have alopecia, and most often are unresponsive to treatment with vitamin D.

The third and more recently recognized genetic cause of rickets designated VDDR-3 is discussed in Chapter 67. In this disease, children with early onset rickets, show reduced serum levels of the vitamin D metabolites  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$ , and deficient responsiveness to vitamin D or its hydroxylated forms [18]. The patients do not have any mutations in the enzymes that cause VDDR-1 rickets or in the VDR that causes HVDRR (VDDR-2A). However, using whole exome sequencing analysis, missense mutations were identified in *CYP3A4*, an enzyme that inactivates vitamin D metabolites [18]. The mutation occurs in the substrate recognition site resulting in a gain of function that substantially increased the ability of the mutant enzyme to specifically inactivate activated vitamin D metabolites. The mutant *CYP3A4* even exhibits twofold greater activity than *CYP24A1*, the major physiological inactivator of vitamin D metabolites. These findings provide insight into vitamin D metabolism and demonstrate that accelerated inactivation of vitamin D metabolites represents a mechanism for vitamin D deficiency [18].

In HVDRR patients the serum  $25(\text{OH})\text{D}$  values may be normal and the  $1,25(\text{OH})_2\text{D}$  levels are elevated, often substantially [9,32]. This singular feature distinguishes HVDRR from  $1\alpha$ -hydroxylase deficiency (VDDR-1A),  $25$ -hydroxylase deficiency (VDRR-1B), and VDDR-3, where the serum  $1,25(\text{OH})_2\text{D}$  values are depressed or even may be undetectable due to loss of *CYP27B1* or *CYP2R1* activity or increased *CYP3A4* activity. Another crucial difference is that patients with VDDR-1A deficiency can be successfully treated with physiologic doses of calcitriol, or  $25(\text{OH})\text{D}$  in the case of VDRR-1B, that bypass the enzymatic defects and restore the circulating  $1,25(\text{OH})_2\text{D}$  levels to normal. In the case of VDDR-3, higher physiologic doses are necessary to treat the condition. In contrast, patients with HVDRR exhibit elevated endogenous levels of  $1,25(\text{OH})_2\text{D}$  and do not respond to additional supra-physiologic doses of calcitriol and most patients are resistant to even extremely

supra-physiologic doses of all forms of vitamin D therapy. However, some patients, mostly with ligand-binding domain (LBD) mutations, may respond to high doses of calcitriol, as described below in Section 6 on Therapy.

HVDRR (VDDR-2A) is inherited as an autosomal recessive disease. The recessive nature of the disease is evident from the patient's parents and most siblings, who are heterozygous for the genetic trait but most often show no symptoms of the disease and have normal bone development. In most cases, consanguinity in the family lineage can be found and intermarriage is highly associated with the disease. Males and females are equally affected and often a family has several affected children [33]. In some unusual cases, there is no history of consanguinity and a different mutation has been inherited from each parent (compound heterozygous mutations). While a majority of cases are due to autosomal recessive transmission, there are now two reports describing autosomal dominant transmission where the mutant VDR exerts dominant negative activity over the wild-type VDR [34,125]. The genetics of VDDR-3 is different. In this condition, the mutations are de novo dominant mutations in the *CYP3A4* gene in affected children from families where the parents and other children do not have mutations in *CYP3A4* or the synthetic enzymes or the *VDR* gene [18].

## 2.2 Pathophysiology

In HVDRR (VDDR-2A), the intestine, and all other vitamin D target organ's including bone, parathyroid glands, and kidneys, are resistant to  $1,25(\text{OH})_2\text{D}$  action. Without vitamin D action, the intestine becomes less efficient in promoting calcium and phosphate absorption into circulation. It is now well established that the biological actions of  $1,25(\text{OH})_2\text{D}$  are mediated by binding to the VDR, a nuclear transcription factor that regulates gene expression in  $1,25(\text{OH})_2\text{D}$ -responsive cells (see several chapters in Section 2 of this volume for details).

Historically, the primary biological processes attributed to vitamin D were the maintenance of calcium and bone homeostasis.  $1,25(\text{OH})_2\text{D}$  is essential for promoting the transport of calcium and phosphate across the small intestine and into the circulation (Chapter 18). Adequate delivery of calcium and phosphate to the bone is essential for the normal mineralization of bone (Chapter 21). Approximately half of the total calcium absorption by the intestine is attributed to  $1,25(\text{OH})_2\text{D}$  action while passive absorption and nonvitamin D-mediated actions account for the remaining half [35,36]. Hypophosphatemia results from the elevated PTH down-regulating the Na/P co-transporter and/or by the loss of a functional VDR in the kidney as well

as decreased intestinal absorption. The absence of an effect of  $1,25(\text{OH})_2\text{D}$  to normally regulate FGF23 or other phosphatonins to normalize phosphaturia and  $1\alpha$ -hydroxylase activity may also play a role (Chapters 19 and 64). The calcium and phosphate deficiencies compromise normal bone mineralization leading to rickets in children and osteomalacia in adults.

There is now a large body of evidence documenting multiple actions of vitamin D in many if not all extra-skeletal organs that are discussed in many chapters of this book. Current evidence for the clinical relevance of some of these actions in patients with HVDRR will be discussed below in [Section 9](#).

## 2.3 Alopecia

Alopecia (sometimes called atrichia) is a clinical feature that is found in many but not all patients with HVDRR. This feature is unique to HVDRR and is not seen in VDDR-1 or VDDR-3 or nutritional vitamin D deficiency. Some affected patients have sparse body hair and some exhibit total scalp and body alopecia in various patterns ([Fig. 68.1](#)) [26,37–39]. Children with extreme alopecia often lack eyebrows and in some cases eyelashes. Hair loss may be evident at birth or occurs during the first few months of life as some hair the child was born with falls out and is not replaced. An analysis of HVDRR patients shows that there is some correlation between the severity of rickets and resistance to vitamin D and the presence of alopecia [39]. Patients with alopecia are generally more resistant to therapy with vitamin D or its more active analogs than those without alopecia. In families with a prior history of the disease, the absence of scalp hair in newborns provides initial diagnostic evidence for HVDRR. The mechanism causing alopecia is being unraveled ([Section 8](#) on Alopecia below and [Chapter 25](#)). However, since VDRs are present in the hair follicle [40,41] and certain mutations in the VDR cause alopecia, but vitamin D deficiency does not, the data indicate a link specifically to the unliganded VDR [42]. A skin biopsy from one patient with HVDRR and alopecia showed apparently normal follicles with no hair [38] while other patients exhibited an absence of normal hair follicles and the presence of follicular remnants and cysts [43,44]. This latter observation led the authors to conclude that the alopecia in HVDRR patients was a phenocopy of generalized atrichia with papular lesions (APL) a genetic disorder caused by mutations in the *hairless* (*hr*) gene [45,46]. Other studies led to further speculation that the VDR and HR converge to regulate similar pathways in the hair cycle [43,44]. A ligand-independent action of the VDR has been proposed to be critical during hair follicle development and therefore mutations in the VDR that

disrupt these ligand-independent actions are suspected to cause alopecia [32,47]. Patients with VDDR-1 or VDDR-3 mutations or with other causes of vitamin D deficiency do not have alopecia, further supporting the role of a ligand-independent action of the VDR during the hair cycle. Alopecia is discussed in more detail below in [Section 8](#) and in [Chapter 25](#).

## 3. Mechanism of $1,25(\text{OH})_2\text{D}$ action relevant to HVDRR (VDDR-2A)

### 3.1 The vitamin D receptor

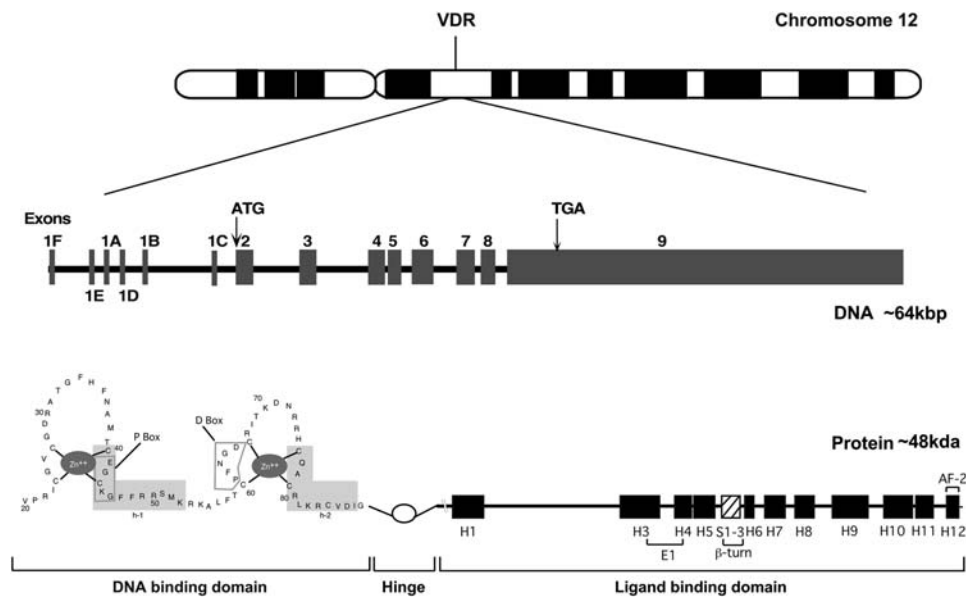

The human VDR gene is located on chromosome 12q13.11 and is composed of 14 exons spanning ~64 kbp of DNA (Chapters 10–13). The human VDR protein is composed of either 427 or 424 amino acids depending upon the presence of a T to C polymorphism (ATG to ACG) in the 427 translational start site that can be identified by an *FokI* restriction site [48,49]. Longer isoforms of 450 and 477 amino acids are also possible due to the differential splicing of exon 1D [50]. The overall structure of the VDR protein is very similar to the other members of the steroid-thyroid-retinoid receptor superfamily.

A highly conserved two zinc-finger DNA-binding domain (DBD) is located in the N-terminus of the VDR ([Fig. 68.2](#)). The DBD is encoded by exons 2 and 3 and is composed of two finger-like modules of 12–13 amino acids each. Four cysteine residues in each finger-like module bind one zinc atom to form the two zinc-finger configuration [51,52]. Specific regions of the DBD are critical for DNA binding, as well as providing a dimerization interface for interaction with the retinoid X receptor (RXR). A nuclear localization signal is also present in the DBD [53,54].

The VDR ligand-binding domain (LBD) is encoded by exons 4–9 [51]. The LBD is composed of 12  $\alpha$ -helices (H1–H12) and 3  $\beta$ -sheets (S1–S3) ([Fig. 68.2](#)) [55]. A hinge region (amino acids 88–122) provides the proper spacing between the DBD and LBD and is important in binding to the nuclear matrix and transcriptional activation [56–58].

### 3.2 Regulation of gene expression by $1,25(\text{OH})_2\text{D}$

The mechanism of action of vitamin D is detailed in multiple chapters in this book. Briefly, after  $1,25(\text{OH})_2\text{D}$  is synthesized in the kidney, it circulates in the blood mostly bound to the vitamin D binding protein (DBP) and perhaps other carriers with a small fraction of hormone in the free state. The free, fat-soluble hormone is believed to enter target cells through the

**FIGURE 68.2** Arrangement of the chromosomal gene and domains of the VDR. The structural organization of the human VDR gene which spans approximately 64 kilobases of DNA is shown [51]. The locations of the start (ATG) and termination (TGA) codons are indicated. The exons encoding the various domains and structural motifs in the VDR protein are shown. The VDR DNA binding domain is comprised of two zinc-finger modules each of which contains 4 invariant cysteine residues that function to coordinate a single zinc atom. Two  $\alpha$ -helices (helix A and B) shaded in the diagram are located on the carboxy-terminal side of each zinc module. Amino acid residues essential to functional interaction of these  $\alpha$ -helices with either DNA or with RXR are boxed and designated the P-box and D-box, respectively. In the ligand-binding domain, the position of the  $\alpha$ -helices (H1–H12) and  $\beta$ -turns (S1–3) are shown as shaded and hatched boxes respectively. The E1 and AF-2 regions are indicated.

lipid bilayer of the cell membrane although additional complex entry mechanisms may play a role, including endocytosis of DBP (see Chapter 7). Many target tissues also possess the enzymatic machinery to synthesize  $1,25(\text{OH})_2\text{D}$  locally within the cell from circulating  $25(\text{OH})\text{D}$  or from cholesterol precursors. Once inside the cell by either pathway,  $1,25(\text{OH})_2\text{D}_3$  binds to the VDR and initiates heterodimerization with RXR and translocation to the nucleus [59]. The ligand-bound VDR-RXR heterodimer binds with high affinity through their respective DBDs to vitamin D response elements (VDREs) located in regulatory regions of target genes [60]. In the LBD,  $1,25(\text{OH})_2\text{D}_3$  makes contact with specific amino acid residues lining the ligand-binding pocket [55] triggering the recruitment of coactivators and other transcription factors [61]. The VDR-RXR coactivator complex then interacts with the general transcription apparatus and drives the transcription of  $1,25(\text{OH})_2\text{D}$ -responsive genes that ultimately determines the cellular response to the hormone. Details of the structural interactions of the hormone with the VDR as well as some HVDRR mutant VDRs are shown and discussed in Chapter 10.

There is some evidence for ligand-independent actions of the VDR [42] which may be the mechanism for VDR mutations causing alopecia. Since alopecia is not found with vitamin D deficiency or other genetic causes of rickets, a role for the unliganded VDR appears to be

the best explanation. This is further discussed in Chapter 25 and below in Section 8 on alopecia.

Proof that the cause of HVDRR is due to defects in the VDR was initially developed through studies of HVDRR patients that showed defective  $1,25(\text{OH})_2\text{D}_3$  induction of target genes such as 24-hydroxylase [62–64]. Mutant VDRs identified in HVDRR patients were incapable of activating VDRE-promoter constructs supporting the critical role of functional VDR in transactivation as well as defining the defects causing HVDRR [65–67]. The development of an animal model of HVDRR by silencing and mutating the VDR was very helpful in understanding the pathophysiology of the HVDRR syndrome as described in Chapter 30.

## 4. Cellular basis of HVDRR (VDDR-2A)

### 4.1 Initial studies using cultured skin fibroblasts

The clinical picture of HVDRR was first recognized as an entity in 1978–79 [20,21,26,68]. Since that time more than 100 patients with HVDRR have been studied and an updated summary of these cases is shown in Table 68.2. Throughout this chapter, the HVDRR cases are denoted by a family number, e.g., F1, F2, etc., and are tabulated with references in Table 68.2. Studies to elucidate the nature of the molecular defect in HVDRR cases began soon after receptors for  $1,25(\text{OH})_2\text{D}$  were

found in the skin [40,154–156]. Feldman et al. [155] demonstrated that the VDR was present in fresh and cultured human foreskin as well as in cultured keratinocytes and dermal fibroblasts grown from adult skin biopsies. The studies to unravel the mutations in HVDRR patients began in earnest after those findings.

Eil et al. [69] showed in cultured skin fibroblasts that the disease was associated with defective nuclear uptake of 1,25(OH)<sub>2</sub>D, although the cause of this defect was not characterized (families F1 and F3). The following year, Feldman et al. [62] analyzed the VDR in cultured skin fibroblasts from two siblings with HVDRR (F11). The authors demonstrated that cytosolic extracts of cultured fibroblasts from these patients exhibited undetectable levels of [<sup>3</sup>H]1,25(OH)<sub>2</sub>D<sub>3</sub> binding. Furthermore, when cultured fibroblasts from normal subjects were treated with 1,25(OH)<sub>2</sub>D they were able to demonstrate an increase in 25-hydroxyvitamin D<sub>3</sub>-24-hydroxylase (24-hydroxylase) activity a well-characterized marker of 1,25(OH)<sub>2</sub>D responsiveness. However, the HVDRR patients' fibroblasts failed to induce 24-hydroxylase activity following treatment with high concentrations of 1,25(OH)<sub>2</sub>D due to defective VDR binding. Subsequently, a number of other HVDRR cases were examined using cultured skin fibroblasts [28,70,71,73,157] or cells derived from bone [83]. Some patients' fibroblasts lacked specific [<sup>3</sup>H]1,25(OH)<sub>2</sub>D binding [28,71,73,83,157] while other fibroblasts exhibited normal [<sup>3</sup>H]1,25(OH)<sub>2</sub>D binding but were nevertheless unresponsive to 1,25(OH)<sub>2</sub>D treatment suggesting defects beyond ligand binding [28,63,73,83,93,158]. Clemens et al. [157] on the other hand, showed that fibroblasts from HVDRR patients were resistant to 1,25(OH)<sub>2</sub>D by demonstrating a loss of the growth inhibitory effects of 1,25(OH)<sub>2</sub>D treatment in contrast to fibroblasts from healthy individuals that were growth-arrested. These early observations demonstrated that cells from HVDRR patients were resistant to 1,25(OH)<sub>2</sub>D and that a spectrum of abnormalities in the VDR could cause resistance. Many other patients with HVDRR have also been reported in the literature [51,78,84,139,140] and the details of these reports can be found in Table 68.2. The Adams et al. paper [84] compared HVDRR patients to those with XLH and the data suggested that VDR binding as well as postreceptor events are normal in patients with XLH.

As the number of reports on HVDRR increased, the heterogeneous nature of the defects in the VDR became more apparent. Hochberg et al. [37,38] reported the clinical findings in four patients from two unrelated families of Arab origin (F11,F18) who exhibited HVDRR and alopecia. A follow-up study by Chen et al. [64] showed that fibroblasts from three of these patients and a patient from an unrelated family from Germany (F17) had no detectable [<sup>3</sup>H]1,25(OH)<sub>2</sub>D-binding and 1,25(OH)<sub>2</sub>D

treatment failed to induce 24-hydroxylase activity. Pike et al. [159] used a radioligand immunoassay [160] and a monoclonal antibody to the chick VDR [161–163], to demonstrate the presence of an immunoreactive VDR protein in cell extracts from fibroblasts of HVDRR patients that exhibited no 1,25(OH)<sub>2</sub>D-binding. The authors speculated that the lack of [<sup>3</sup>H]1,25(OH)<sub>2</sub>D-binding in these patients was not due to defective synthesis of the VDR protein but was due to defects in the VDR LBD that abolished 1,25(OH)<sub>2</sub>D-binding [159]. Castells et al. [76] reported on a patient (F22) who had sparse hair, rickets, and high circulating 1,25(OH)<sub>2</sub>D levels. Studies of the VDR from the patient's fibroblasts showed that the VDR had decreased affinity for [<sup>3</sup>H]1,25(OH)<sub>2</sub>D. The patient showed a marked improvement after treatment with extremely high doses of 1,25(OH)<sub>2</sub>D apparently overcoming the low affinity binding abnormality in the LBD.

Based on the hypothesis that VDR binding to DNA was essential for its activity, Hirst et al. [63] examined whether defective VDR binding to DNA could be the cause of resistance in cases where the VDR exhibited normal ligand-binding. In a study of a family from Haiti (F19) with two sisters with clinical HVDRR and a normal unaffected sister, the authors showed that the fibroblasts from the two affected sisters had normal [<sup>3</sup>H]1,25(OH)<sub>2</sub>D-binding but were resistant to 1,25(OH)<sub>2</sub>D treatment. The authors further demonstrated that the VDR from the patient's fibroblasts exhibited a significant decrease in its affinity for DNA. A subsequent study by Malloy et al. [93] demonstrated a similar DNA binding defect in the VDR from HVDRR patients (F31) who had normal [<sup>3</sup>H]1,25(OH)<sub>2</sub>D binding. DNA-cellulose chromatography clearly revealed that the patient's VDR had a low affinity for DNA. Furthermore, the cells from the parents expressed two forms of the VDR, one with a high affinity for DNA and the other with a low affinity for DNA, the same as the affected daughters. This was the first evidence demonstrating the presence of the defective and normal VDR in cells from parents of HVDRR children. It was hypothesized that the VDR defects in these cases were likely be due to mutations in the VDR DBD [63,93], that later proved to be correct [65].

## 4.2 Studies in other cell types

A number of other cell types have been used to study the VDR in HVDRR patients. These include peripheral mononuclear cells [89], phytohemagglutinin (PHA)-stimulated lymphocytes [164,165], myeloid progenitor cells [90], Epstein–Barr virus (EBV) immortalized B lymphoblasts [33,65,66,93], and HTLV-1 virus immortalized T lymphoblasts [96]. It is interesting to note that although EBV immortalized B lymphoblasts from

### Mutations in the VDR DNA binding domain

**FIGURE 68.3** Model of the DNA-binding domain (DBD) of the VDR and location of mutations causing HVDRR. The two zinc-finger modules and the amino acid composition of the DBD are shown. Conserved amino acids are depicted as shaded circles. Numbers specify amino acid number.

normal subjects expressed wild-type VDR, they failed to induce 24-hydroxylase activity, and their growth was not inhibited by  $1,25(\text{OH})_2\text{D}$  [33]. A possible mechanism for these early findings was elucidated by Yenamandra et al. who showed that EBNA-3 a member of the EBNA-3-protein family that regulate transcription of cellular and viral genes, blocked the activation of VDR-dependent genes and protected the EBV immortalized lymphoblasts against vitamin- $\text{D}_3$ -induced growth arrest [166]. In contrast, PHA-stimulated lymphocytes and HTLV-1 immortalized T lymphoblasts from normal subjects do respond to  $1,25(\text{OH})_2\text{D}$  [96,167]. Takeda et al. [165] used PHA-stimulated lymphocytes from HVDRR patients to demonstrate  $1,25(\text{OH})_2\text{D}$  resistance by its failure to inhibit DNA synthesis or induce 24-hydroxylase activity [164,165]. Takeda et al. [165] also showed that PHA-stimulated lymphocytes from parents of children with HVDRR expressed intermediate levels of 24-hydroxylase in response to  $1,25(\text{OH})_2\text{D}$  compared to normal cells.

## 5. Mutations that cause HVDRR (VDDR-2A)

### 5.1 First description of a genetic defect in the nuclear receptor superfamily

The biochemical and cellular data obtained from the earlier studies of HVDRR patients provided a framework to begin the search for the specific molecular defect that inactivated the VDR and caused the disease. Investigations to determine the molecular nature of the mutations in the VDR that led to HVDRR began shortly after the human VDR cDNA sequence was elucidated by Baker et al.

[168]. During this same time period, the polymerase chain reaction (PCR) [169] was discovered that provided a method to amplify DNA for sequence analysis. The amino acid sequence of the VDR derived from the sequencing of the VDR cDNA suggested the presence of highly conserved zinc-finger structures that were thought to be involved in VDR binding to DNA. The initial sequencing studies focused on HVDRR patients with normal  $[^3\text{H}]1,25(\text{OH})_2\text{D}$  binding but abnormal binding to DNA since it was suspected that this defect would arise from mutations in the VDR DBD. In 1988, Hughes et al. [65] used PCR to amplify exons of the VDR gene from DNA isolated from the F19 and F31 families that were defective in DNA binding [63]. Patients in the F19 family were shown to have a unique G to A single base change in exon 3 that replaced arginine with glutamine at amino acid residue 73 (Arg73Gln) in the second zinc finger module of the DBD (Fig. 68.3). In the F31 family, a G to A transition was identified in exon 2 that changed glycine to aspartic acid at amino acid residue 33 in the first zinc finger module (Gly33Asp) (Fig. 68.3). The mutant sequences were only found in the children with HVDRR while their parents had a normal and mutant sequence demonstrating the genetic transmission and recessive nature of the disease. The study by Hughes et al. [65] was the first description of a genetic defect in a member of the steroid-thyroid-retinoid receptor gene superfamily. Mutations have now been found in many of the classical nuclear receptors including thyroid, androgen, estrogen, progesterone, glucocorticoid, and mineralocorticoid receptors.

To demonstrate that the Arg73Gln and the Gly33Asp mutations found in these families were the cause of

1,25(OH)<sub>2</sub>D resistance in the HVDRR patients, the mutations were recreated in the wild-type VDR cDNA by site-directed mutagenesis [67]. The mutant VDRs expressed in COS-1 cells exhibited normal [<sup>3</sup>H] 1,25(OH)<sub>2</sub>D-binding but weak binding to DNA similar to the VDR in the patient's fibroblasts. Importantly, in CV-1 cells, cotransfection with an osteocalcin-CAT reporter plasmid, showed that CAT activity could be induced by the wild-type VDR but not by the Arg73Gln or the Gly33Asp mutant VDRs. These data proved that the missense mutations caused the VDR to be transcriptionally inactive and were the cause of 1,25(OH)<sub>2</sub>D<sub>3</sub> resistance in the patients [67].

Since the original report of the genetic abnormality causing HVDRR by Hughes et al. [65] over 100 cases of HVDRR have been recorded and a number of these have been analyzed at the biochemical and molecular level (Table 68.2). Many different genetic abnormalities have now been identified in the VDR gene, including missense and nonsense mutations, but also deletions and splice site mutations. A description of these mutations and effects on VDR function is discussed below. Chapter 10 discusses in greater detail the structural defects in some of the HVDRR mutations and the mechanism by which the mutation impairs the function of the VDR to activate target genes.

## 5.2 Mutations in the VDR DNA binding domain (DBD)

Since the initial report by Hughes et al. [65], a number of mutations have been identified in the VDR DBD. The location of these mutations within the DBD is illustrated schematically in Fig. 68.3. Sone et al. [75] examined the VDR from two unrelated patients (F5 and F20) previously shown to exhibit a ligand-binding positive and low affinity DNA-binding phenotype by Liberman et al. [71,158]. In both patients, a mutation was identified that changed arginine to glutamine in the second zinc-finger module (Arg80Gln). The recreated Arg80Gln mutant VDR had a high affinity for binding [<sup>3</sup>H] 1,25(OH)<sub>2</sub>D, but had a lower affinity for DNA binding than WT DNA and was unable to activate gene transcription from a reporter plasmid demonstrating that this molecular defect was the cause of HVDRR in these cases [75]. Malloy et al. [102] also identified the same Arg80Gln mutation in two siblings with HVDRR (F49). The F49 family and the families (F5, F20) described by Sone et al. [75] both had origins in North Africa, however, no genetic relationship between these families could be established. This mutation was also identified in a female patient (F126) described by Nicolescu et al. [148].

Saijo et al. [49] found an Arg50Gln mutation in two unrelated families F26 and F33 while Yagi et al. [100]

identified a His35Gln mutation in family F45. Rut et al. [98] identified a Lys45Glu mutation in family F44 [99] and a Phe47Ile mutation in family F47 [101]. The Lys45Glu was subsequently found in seven patients in five families F107 [138], and F119, F120, F121, F122 [147].

Lin et al. [87] examined the VDR gene for mutations in a patient (F23) with HVDRR previously described by Sakati et al. [88]. A unique G to A base change resulted in a glycine being changed to aspartic acid at amino acid 46 (Gly46Asp) in the VDR DBD. In contrast to the other DBD mutations described above, the mutation at Gly46 occurs in an amino acid that is not well conserved in the steroid-thyroid-retinoid receptor superfamily. However, Gly46 is conserved among receptors that form heterodimers with RXR proteins such as thyroid receptor (TR) and retinoic acid (RAR) receptor. Additional unique missense mutations identified in the VDR DBD include a Val26Met mutation in family F69 [23], a Cys41Tyr mutation in families F77 and F111 [119,141], a Cys60Trp mutation in family F105 [126], an Arg80Trp mutation in family F143 [152], and a Cys84Arg mutation in family F80 [120].

The Lys45Glu and Gly46Asp mutations are located in the P-box (Fig. 68.2). This region of the VDR DBD is likely important in contacting the DNA bases and determining the specificity of the receptor for specific VDREs. Rut et al. [98] proposed that the Lys45Glu mutation would disturb the hydrogen bonding between Lys45 and a guanine nucleoside in the VDRE half-site and eliminate the ability of the VDR to interact with VDREs. The loss of the phenylalanine ring structure caused by the Phe47Ile mutation would disrupt the integrity of the hydrophobic core of the VDR DBD thereby altering binding to VDREs (Fig. 68.3) [98]. The Cys41Tyr and Cys60Trp mutations likely disrupt the coordination of the zinc ion and the formation of the zinc-finger structure. The Arg50Gln mutation occurs in the nuclear localization signal (NLS) that could inhibit the translocation of the VDR to the nucleus [54]. The Val26Met mutation likely disrupts the topography of the first zinc-finger module preventing binding to VDREs [23] while the Cys84Arg mutation may disrupt the alpha-helical structure of h-2 proposed at the base of the second zinc-finger module (Fig. 68.2). Arg80 directly forms hydrogen bonds with the backbone of the DNA in DNA-VDR complexes, and these hydrogen bonds were no longer present in DNA-VDR Arg80Trp complexes [152].

## 5.3 Mutations causing premature termination of the VDR

### 5.3.1 Nonsense mutations

Nonsense mutations in the VDR gene that introduce a premature stop signal cause early termination of the

mature VDR protein. The first molecular analysis of three HVDRR cases (F18, F34, F36) [64,80,170] that exhibited no [ $^3\text{H}$ ]1,25(OH) $_2\text{D}$ -binding was reported by Ritchie et al. [66]. A single unique C to A base change was found in exon 7 that changed the codon for tyrosine (TAC) to an ochre termination codon (TAA) (Tyr295stop) (Fig. 68.4). The location of the premature stop at amino acid 295 truncates 132 amino acids of the carboxy terminus of the VDR that result in the deletion of a major portion of the LBD thereby creating the ligand-binding negative phenotype. The Tyr295stop mutation was the first nonsense mutation identified in the VDR. The location of this mutation and other nonsense mutations that cause premature termination of the VDR is shown in Fig. 68.4 and summarized in Table 68.2.

The three families studied by Ritchie et al. [66] and four additional families (F35, F37, F38, and F39) that comprised a large kindred in a region where consanguineous marriages were common were analyzed by Malloy et al. [33] (Table 68.2). A total of 8 children from this kindred exhibited HVDRR with alopecia. All of the affected children were homozygous for the Tyr295stop mutation and their parents were

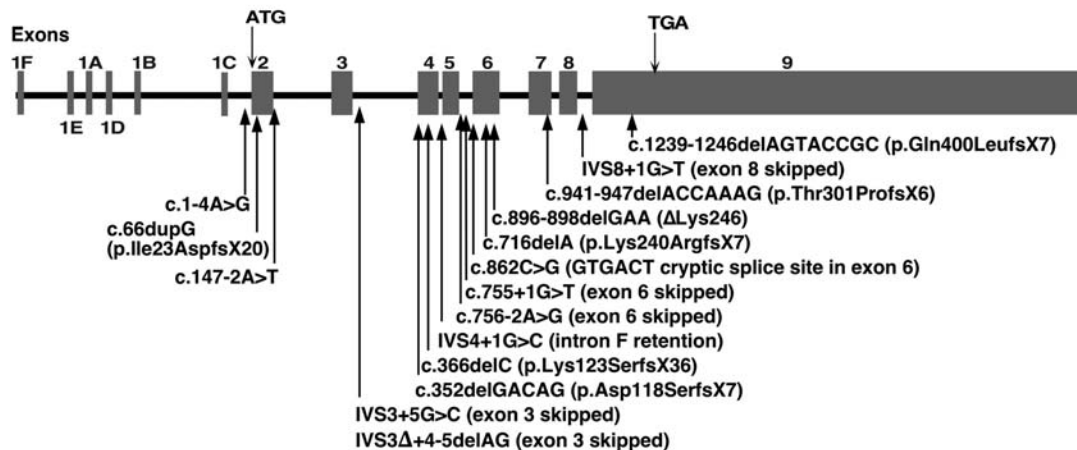

heterozygous. Interestingly, the 32,000 molecular weight truncated protein that is predicted to be produced by this mutation could not be detected in extracts of cultured dermal fibroblasts using Western blots. In addition, in all but one case, the VDR mRNA was undetectable on the Northern blot using RNA isolated from the cultured fibroblasts or EBV-transformed lymphoblasts from the patients. The absence of VDR mRNA indicated that the Tyr295stop mutation likely led to nonsense-mediated mRNA decay and, in this case, accounts for the absence of the mutant VDR protein [33]. This kindred is part of the Tiosano et al. cohort discussed later in Section 7.

The Tyr295stop mutation was also identified in patients (F29, F30) [92], in an Egyptian child (F91) [129], in two children in family F11 described in earlier papers [37,38,62,64,82] and in eight patients from four unrelated families with a history of consanguinity (F127, F128, F129, F130) [149]. A patient with HVDRR (F46) with no [ $^3\text{H}$ ]1,25(OH) $_2\text{D}$ -binding had a premature stop codon at amino acid 73 (Arg73stop) (Fig. 68.4) [92]. The Arg73-stop mutation was also identified in patients from families F55, F76, F96, and F102 [108,131,135]. Interestingly,

#### Stop mutations

#### Splicing mutations duplications deletions

**FIGURE 68.4** Splice site, duplication, and deletion mutations in the VDR. The locations of the nonsense mutations in the VDR protein shown (top figure). Lower figure shows the location of splice site and duplications/deletions mutations in the VDR gene.

the patient from family F96 was a 2-year-old girl with alopecia, short stature, and rickets without a family history of consanguinity. The child was homozygous for the nonsense mutation that caused the Arg73stop. Her mother was heterozygous for the mutation, but her father was negative. The authors excluded gross deletion of the father's allele or paternal discordance. Genome-wide SNP array of the family (the patient and her parents) showed complete maternal isodisomy of chromosome 12. The patient was successfully treated with high-dose oral calcium. This was the first reported case of Uniparental Disomy involving chromosome 12 [131].

A number of other premature stop mutations have been identified in the VDR and the locations of these mutations are shown in Fig. 68.4. The premature stop mutations causing HVDRR include an Arg30stop mutation in families F53 [106], F54 [107], F64, F89 [128], and F90 [129], and a Gln152stop mutation in families F32 [72,92], F103 [136], F131 and F132 [150], F135 and F142 [151]. Interestingly, the parents in family F32 who were first cousins and heterozygous for the Gln152stop mutation had elevated levels of serum 1,25(OH)<sub>2</sub>D. The mean value for the father was 73 pg/mL and for the mother 93 pg/mL (normal range 20–80 pg/mL). The elevated 1,25(OH)<sub>2</sub>D values raise the possibility of mild vitamin D resistance in the heterozygotic parents, a finding that had not been documented previously in other parents of HVDRR children. A young Iranian girl (F61) with HVDRR and alopecia was reported by Bouillon and Vainsel [171]. The patient's fibroblasts expressed the VDR mRNA but had no VDR protein and were unresponsive to high doses of 1,25(OH)<sub>2</sub>D<sub>3</sub>. Sequence analysis of the VDR gene uncovered a glutamine being replaced by a termination codon (Gln317stop) (Fig. 68.4) [111]. Forghani et al. [24] studied two unrelated patients (F78, F79) with HVDRR and alopecia living in different parts of the USA. Both patients had a mutation that changed arginine at amino acid 50 to a stop codon (Arg50stop). The Arg50stop mutation was also found in families F98 and F113 [132]. Two Greek patients (F104) with HVDRR and alopecia had a mutation that changed glutamine at amino acid 356 to a stop codon (Gln356stop) [137].

### 5.3.2 Mutations that disrupt mRNA splicing

Hawa et al. [103] examined the VDR in a young Greek girl (F50) with HVDRR and alopecia. They showed that the patient's RNA sequence diverged from the wild-type sequence at nucleotide 147. The sequence from exon 3 that encodes the second zinc finger module was deleted and the sequence that followed was from exon 4. Sequence analysis of the VDR chromosomal gene found no mutations in the exons, however, a G to C base change was found in the 5' end of intron E (Fig. 68.4). This single nucleotide change converted the

wild-type sequence from GTGAGT to GTGACT and eliminated the 5' donor splice site (IVS3+5G > C). The loss of the 5' donor splice site caused exon 3 to be skipped causing a reading frameshift that resulted in a premature stop codon. The mutant protein contained 92 amino acids of the wild-type sequence plus 6 amino acids due to the frameshift (Glu92fsX7). This mutation was also found in a patient from family F99 [133].

A young Thai girl (F82) with partial alopecia had a single base substitution in the 5'-donor splice site at the exon 4-intron F junction [122]. The mutation caused 254 base pairs of intron F to be incorporated into the VDR mRNA (IVS4+1G > C). The encoded VDR protein contained 154 amino acids of the wild-type sequence and an additional 23 amino acids from the unspliced intron F. A splice site mutation was also identified in a young Hispanic girl (F72) with HVDRR and partial alopecia. A novel G to T substitution was identified in the 5'-splice site in the exon 8-intron J junction (IVS8+1G > T) [117]. Sequence analysis showed that exon 8 was skipped and that exons 7 and 9 were fused in the frame. However, the mutation caused a 39 amino acid deletion ( $\Delta$ Ala303-Pro341) in the VDR LBD. The recreated mutant VDR $\Delta$ Ala303-Pro341 was unable to activate gene transcription (Malloy unpublished study). A young child (F100) with HVDRR and alopecia was shown to have an A to T substitution that caused a splice site mutation (c.147-2A > T) [134].

Other splice site mutations have been identified (Fig. 68.4). Cockerill et al. [108] described a patient (F56) with a C to G mutation at nucleotide position 702 that generated a cryptic 5' splice site leading to the removal of part of exon 7. The mutant protein contained 233 amino acids of the wild-type sequence and an additional 4 amino acids due to a frameshift (Leu233fsX5). A young girl (F133) from Turkey had a novel mutation in the consensus splice acceptor site (c.756-2A > G), that resulted in abnormal splicing [150]. Demir et al. [151] identified two splice site mutations in the VDR gene. In one patient (F138) a novel c.1-4A > G mutation located in the canonical splice acceptor site of intron 3 and was predicted to cause the skipping of exon 2, which contains the first coding exon of the VDR gene. In a second patient (F139) a c.755+1G > T mutation located in the canonical splice donor site of intron 8 and was predicted to cause exon 8 skipping.

### 5.3.3 Deletions

Deletion mutations are shown in Fig. 68.4. In a preliminary report of patient (F42), a major structural defect in the VDR gene was described as the cause of HVDRR [97]. The defect, found by PCR and Southern blotting, was a deletion in the VDR gene that eliminated exons 7–9. A young girl from India with HVDRR and alopecia was found to have a one bp deletion in exon 6

(c.716delA) [121]. The mutation caused a shift in the reading frame that introduced a premature stop codon and resulted in the truncation of the VDR LBD (p.Lys240ArgfsX7). A second girl (F101) from India had a 2 bp (AG) deletion in the 5'-donor splice site at the exon 3-intron E boundary (IVS3Δ+4-5 del AG) [126]. The mutation likely caused exon 3 skipping. One patient (F141) was shown to have a five base deletion (c.352delGACAG) resulting in an Asp118Ser mutation and frameshift resulting in a premature stop codon seven amino acid downstream (p.Asp118SerfsX7) [151]. All of the nonsense mutations and all splice site mutations that lead to frameshifts, as well as the gene deletion mutations result in truncated VDRs. Although some of the mutant VDRs may have intact DBDs, the loss of the LBD and therefore its ability to bind 1,25(OH)<sub>2</sub>D, or associate with RXR, and interact with coactivators makes the mutant receptors nonfunctional and causes complete hormone resistance.

## 5.4 Mutations in the VDR ligand-binding domain (LBD)

### 5.4.1 Mutations that affect 1,25(OH)<sub>2</sub>D<sub>3</sub>-binding

LBD mutations are illustrated in Fig. 68.5. Rut et al. [85] and Kristjansson et al. [86] identified the first missense mutation in the VDR LBD. The patient from Kuwait (F21) had HVDRR but did not have alopecia. Preliminary studies by Fraher et al. [31] on the patient's fibroblasts showed absent [<sup>3</sup>H]1,25(OH)<sub>2</sub>D<sub>3</sub>-binding. However, Rut et al. [85] later showed that the fibroblasts contained normal amounts of [<sup>3</sup>H]1,25(OH)<sub>2</sub>D-binding but the affinity of the receptor for 1,25(OH)<sub>2</sub>D was significantly reduced ( $K_d$   $1 \times 10^{-9}$  M) compared to normal controls ( $K_d$   $0.7 \times 10^{-10}$  M). They showed that the

patient's fibroblasts were resistant to vitamin D by their failure to induce 24-hydroxylase activity when treated with high doses of 1,25(OH)<sub>2</sub>D [31,85]. Molecular analysis of the VDR gene identified a unique G to T missense mutation in exon 7 that replaced arginine residue with leucine at amino acid 274 (Arg274Leu) (Fig. 68.5) [85,86]. As described by Rochel et al. [55] and discussed in Chapter 10, Arg274 is a contact point for the 1 $\alpha$ -hydroxyl group in 1,25(OH)<sub>2</sub>D. In transactivation assays, the recreated Arg274Leu mutant VDR was relatively resistant to vitamin D requiring approximately 1000-fold more 1,25(OH)<sub>2</sub>D to activate gene transcription than the wild-type receptor [86]. Although the resistance caused by the defective VDR could be overcome by treating with high concentrations of 1,25(OH)<sub>2</sub>D in vitro, the patient failed to respond to massive doses of the hormone and eventually died of pneumonia.

An Arg274His mutation was identified in two unrelated children (F84, F85) from the United Arab Emirates with HVDRR without alopecia by Aljubeih et al. [124]. In transactivation assays, both the Arg274Leu and Arg274His mutants showed ~100-fold lower responsiveness to 1,25(OH)<sub>2</sub>D compared to the WT VDR. Whitfield et al. [74] analyzed the VDR from a girl (F4) who had the classic symptoms of HVDRR but without alopecia. The patient's fibroblasts had normal 1,25(OH)<sub>2</sub>D<sub>3</sub> binding but had defective induction of 24-hydroxylase activity [73]. Sequencing of the VDR gene uncovered a T to G substitution in exon 8 that changed isoleucine to serine at amino acid 314 (Ile314Ser) (Fig. 68.5). The Ile314Ser mutation caused a subtle defect in RXR heterodimerization and decreased response to 1,25(OH)<sub>2</sub>D in vitro [74]. Interestingly, the patient showed a nearly complete cure of rickets when treated with pharmacological doses of 25(OH)D.

**FIGURE 68.5** Schematic illustration of the ligand-binding domain (LBD) of the VDR and location of missense mutations that cause HVDRR. The  $\alpha$ -helices (H1–H12) of the VDR LBD are depicted as shaded rectangles and the  $\beta$ -turns are drawn as a hatched rectangle. The loops connecting the helices are drawn as solid lines. The E1 and AF-2 regions are shown below the  $\alpha$ -helices.

A His305Gln missense mutation in the VDR LBD was described by Malloy et al. [104]. The patient a Turkish boy (F51), had HVDRR and two other rare disorders, congenital generalized lipomatrophic diabetes (Berardinelli-Seip syndrome), and Persistent Müllerian Duct Syndrome (PMDS) [105]. The patient had rickets and elevated 1,25(OH)<sub>2</sub>D levels but did not have alopecia. He was treated with extremely high doses of calcitriol (Rocaltrol 12.5 µg/day) that eventually normalized his serum calcium and ultimately improved his rickets. However, the child died of apparently unrelated problems. In vitro the patient's fibroblasts expressed normal VDR levels but the affinity for 1,25(OH)<sub>2</sub>D was decreased by about twofold. The patient's fibroblasts required approximately a fivefold more 1,25(OH)<sub>2</sub>D to induce *CYP24A1* mRNA compared to control cells. In gene transactivation assays, the His305Gln mutant VDR required fivefold more 1,25(OH)<sub>2</sub>D to achieve the same level of activity as the wild type VDR. The boy's sister, who also had HVDRR and the same mutation in the VDR, did not exhibit the other two genetic defects her brother had. No explanation was forthcoming for the presence of three genetic defects in a single individual. It is unclear how the His305Gln mutation in the VDR is related, if at all, to the two other genetic abnormalities that were present in this child. The congenital total lipodystrophy was subsequently shown to be due to a mutation in the seipin gene (*BSCL2*) [172]. While a genetic cause for the PMDS was not determined, Malloy et al. have shown that Müllerian-inhibiting substance (MIS) is regulated by the VDR [173]. Since MIS initiates the regression of the Müllerian ducts that in a normal female embryo develop into the uterus, fallopian tubes, and upper vagina, and in males also controls the induction of the abdominal phase of testicular descent [174]. One might speculate that PMDS was due to the VDR mutation causing lack of Müllerian duct regression in this child. However, the fact that PMDS has not been reported in other children with inactivating VDR mutations, or in the sister with the same mutation, makes it unlikely to be the cause.

Other LBD mutations that affect 1,25(OH)<sub>2</sub>D binding are shown in Fig. 68.5. An Algerian boy and his younger sister (F59) both with HVDRR without alopecia were shown to have a Trp286Arg mutation (Fig. 68.5) [110]. A young Saudi Arabian girl (F63) with HVDRR but without alopecia was found to have a Ile268Thr mutation [112]. The Ile268Thr mutant VDR exhibited a ~10-fold lower affinity for [<sup>3</sup>H]1,25(OH)<sub>2</sub>D binding compared to the WT VDR. However, in transactivation assays, the Ile268Thr mutant required ~100-fold higher concentrations of 1,25(OH)<sub>2</sub>D to stimulate gene transcription compared to the WT VDR. The Ile268Thr mutation was also identified in a boy (F140) with HVDRR

without alopecia [151]. A Saudi Arabian boy with HVDRR without alopecia was shown to have an Asp144Asn mutation in the VDR LBD [126]. In transactivation assays, the recreated Asp144Asn mutant was ~33-fold less responsive to 1,25(OH)<sub>2</sub>D compared to the WT VDR. A young boy (F95) from Macedonia with HVDRR without alopecia was found to have an Arg158Cys mutation in the VDR LBD [126]. The patient's fibroblasts exhibited a minimal response to 100 nM 1,25(OH)<sub>2</sub>D. An Arg158Leu mutation was also identified in a boy (F137) with HVDRR without alopecia [151].

A young boy (F94) with HVDRR without alopecia was found to have a Leu227Pro mutation in the LBD [130]. In transactivation assays the recreated Leu227Pro mutant exhibited little to no activity when treated with 1 µM 1,25(OH)<sub>2</sub>D. A Turkish girl (F112) with HVDRR with alopecia was shown to have a Ser360Pro mutation in the VDR LBD. Functional studies showed that the Ser360Pro mutant had no [<sup>3</sup>H]1,25(OH)<sub>2</sub>D binding and failed to interact with RXR and coactivators SRC-1 and N-CoR [142]. The detailed structural analysis of some LBD and other VDR mutations that affect 1,25(OH)<sub>2</sub>D binding or activity is further discussed in Chapter 10.

#### 5.4.2 Mutations that affect VDR-RXR heterodimerization

As discussed previously, the VDR requires heterodimerization with RXR for gene regulation activity. Disruption of the protein:protein interaction with RXR can thereby cause 1,25(OH)<sub>2</sub>D resistance. These mutations are illustrated in Fig. 68.5. The first patient found to have a mutation in the VDR that disrupted VDR-RXR heterodimerization was described by Whitfield et al. [74]. The patient a young girl (F52) with HVDRR and alopecia, was found to have a mutation that changed arginine to cysteine at amino acid 391 (Arg391Cys). Ligand binding was normal but transactivation of a reporter gene by the Arg391Cys mutant VDR required higher than normal concentrations of 1,25(OH)<sub>2</sub>D for activity. However, when RXR was cotransfected in the assays the transactivation activity could be restored to normal levels. In electrophoretic mobility shift assays (EMSA) the Arg391Cys mutant exhibited a lower capacity for forming a VDR-RXR-VDRE complex than the wild-type VDR. This study demonstrated the importance of both 1,25(OH)<sub>2</sub>D-binding and RXR heterodimerization in VDR-mediated gene transactivation. The fact that the girl had alopecia was instructive in that disruption of VDR-RXR dimerization, can cause alopecia. This finding is also noted in the following cases substantiating the point.

An Arg391His mutation was identified in an Egyptian child (F93) [129] and an Arg391Ser (F116, F117) was found in three Lebanese patients from two families

(F116, F117) [145]. Like the patient with the Arg391Cys mutation, these children also had alopecia. Two siblings, a brother and sister from India (F57) that had HVDRR with alopecia, had a missense mutation that changed glutamine to proline at amino acid 259 (Gln259Pro) [108] (Fig. 68.5). Although Gln259Pro had no apparent effect on ligand binding there was evidence of impaired VDR-RXR-VDRE formation. In two Brazilian patients (F73, F75) with HVDRR and alopecia, a missense mutation was found that changed Gln259 to aspartic acid (Gln259Asp) [118]. Like the Gln259Pro mutation, the Gln259Asp mutation would also be predicted to affect heterodimerization with RXR.

Malloy et al. [109] examined the VDR in a young Hmong boy (F58) with HVDRR and alopecia. A unique missense mutation was found that changed a phenylalanine to cysteine at amino acid 251 (Phe251Cys) (Fig. 68.5). In [ $^3\text{H}$ ]1,25(OH) $_2\text{D}_3$  binding experiments, the recreated Phe251Cys mutant VDR exhibited a lower affinity for the ligand than wild-type VDR. In GST pull-down assays and yeast two-hybrid assays, the Phe251Cys mutant VDR was shown to have a reduced capacity to bind RXR. In transactivation assays, co-transfection of RXR partially restored the activity of the mutant receptor. The Phe251Cys mutation occurs in the E1 region (amino acids 244–263) of the VDR LBD. The E1 region overlaps the C-terminal portion of helix H3, loop 3-4 and the N-terminal portion of helix H4.

Two patients (F74, F97) with HVDRR and alopecia were shown to have a mutation that changed glycine to valine at amino acid 319 (Gly319Val) [118,128]. Damiani et al. [128] noted that their patient had normal bone mass and normocalcemia in adulthood despite homozygous vitamin D receptor mutations. Gly319 is part of the dimerization interface (residues 317–325) of the VDR that interacts with RXR [175]. A Val346Met mutation was identified in Bedouin boy with HVDRR and alopecia [114]. The patient also had papular lesions on the scalp and face. Two brothers and one sister were also affected. The affected children also had mild hearing loss and secondary speech abnormalities. Although hearing loss had not been noted before in other HVDRR patients, progressive hearing loss was found in VDR knockout mice [176].

#### 5.4.3 Mutations that affect coactivator-binding

As noted above, the VDR also must recruit coactivator proteins for transcriptional activity. It is now clear from crystallographic studies of the VDR and other members of the steroid receptor superfamily that repositioning of helix H12 is an essential event that occurs as a consequence of ligand binding and is required for transactivation [55]. The repositioning of helix 12 leads to the formation of the hydrophobic cleft critical for coactivator

binding. Therefore, disruption of this surface interface may cause hormone resistance and HVDRR.

A study by Malloy et al. [32] examined the VDR in a young boy (F60) with HVDRR without alopecia. The patient's fibroblasts exhibited normal ligand binding but the cells were totally resistant to 1,25(OH) $_2\text{D}$  action. A novel missense mutation was found in exon 9 that changed a glutamic acid to lysine at amino acid 420 (Glu420Lys) (Fig. 68.5). The Glu420Lys mutation is located in helix H12. The recreated Glu420Lys mutant VDR showed no defects in VDR-RXR heterodimerization or binding to VDREs. However, the mutation prevented the coactivators SRC-1 and DRIP205 from binding to the VDR. In transactivation assays, cotransfection of SRC-1 failed to restore transactivation by the mutant VDR. This case represented the first description of a naturally occurring mutation in the VDR that disrupts coactivator interactions and causes HVDRR [32]. The polar interactions that stabilize the repositioning of helix H12 involve a conserved salt-bridge between Lys264 in helix H4 and Glu420 in helix H12 and a hydrogen bond between Ser235 in helix H3 and Thr415 in helix H12 [55]. The substitution of the negatively charged glutamic acid (Glu420) with a positively charged lysine (Lys420) would prevent the polar interaction with the positively charged lysine (Lys264) salt bridge partner. The charge clamp formed by Lys264 and Glu420 enables the VDR to recruit and bind coactivators through their LxxLL motifs. The Glu420Lys mutation prevents the correct repositioning of helix H12 after binding the ligand that disrupts coactivator binding and causes the hormone resistance seen in the patient.

An Egyptian child (F92) with HVDRR and alopecia was found to have a mutation that changed arginine to cysteine at amino acid 343 (Arg343Cys) [129]. A second mutation in the Arg343 residue (Arg343His) was identified in a patient (F118) with alopecia [146]. Interestingly, Arg343 resides in helix H9 and is important in RXR heterodimerization. However, functional analysis of the Arg343His mutant VDR showed no apparent defect in RXR heterodimerization. Modeling studies indicate that the Arg343 residue contacts Glu269 of the H5 structure of VDR, which is important in the formation of a hydrophobic cleft with H3 and H4 that forms binding sites for transcriptional coactivators and co-repressor molecules. In support of this, the addition of GRIP-1 did not rescue transactivation by the Arg343His mutant VDR. These results suggest that mutations that cause instability of the H5 structure of VDR can result in alopecia.

A Lebanese boy (F115) without alopecia was shown to have a His397Pro mutation [145]. The patient later presented with multi-lobar pneumonia and died of cardiopulmonary arrest. His397 is involved in stabilizing

helix H12 positioning and thus the His397Pro mutation likely disrupts coactivator binding. A patient (F123) without alopecia was found to have a Thr415Arg mutation [147]. Thr415 is also involved in stabilizing helix H12 positioning and the Thr415Arg mutation likely disrupts coactivator binding.

## 5.5 Compound heterozygous mutations in the VDR

There are several reports of patients with HVDRR with compound heterozygous mutations in the VDR gene. There is no consanguinity in these patient's families and the asymptomatic parents each harbor a mutation in one allele of their VDR gene that is passed to their offspring. In patient (F62) with HVDRR and alopecia a heterozygous missense mutation was found that caused a Glu329Lys substitution (Fig. 68.5) [44]. The patient was also heterozygous for a mutation in exon 4 that deleted a single cytosine at nucleotide 366 (c.366delC). The c.366delC deletion resulted in a frameshift that led to a premature termination signal that truncated the VDR (p.Lys123SerfsX36) (Fig. 68.4).

Compound heterozygous mutations were also identified in the VDR gene in a child (F68) with HVDRR, total alopecia, and early childhood-onset type 1 diabetes [115]. A missense mutation was found in exon 7 that caused a Leu263Arg substitution in helix H4. A second missense mutation was found in exon 9 that caused an Arg391Ser substitution in helix H10. As described above, an Arg391Cys mutation was previously shown to affect RXR heterodimerization thus it was likely that the arginine to serine substitution also affected heterodimerization [74]. Interestingly, the Leu263Arg mutant and the Arg391Ser mutant VDRs exhibited differential activity on 24-hydroxylase and RelB promoters. The 24-hydroxylase responses were abolished in the Leu263Arg mutant but only partially altered in the Arg391Ser mutant. On the other hand, RelB responses were normal for the Leu263Arg mutant but the Arg391Ser mutant was defective in this response [115].

Compound heterozygous mutations were also identified in a young girl (F70) with HVDRR and alopecia [22]. One mutation changed the codon for arginine to a nonsense mutation at amino acid 30 (Arg30stop). The second mutation was an in-frame 3-bp deletion in exon 6. The 3-bp deletion (c.896-898delGAA) removed the codon for lysine (GAA) at amino acid 246 ( $\Delta$ K246) but did not alter the reading frame (Fig. 68.4). The patient's fibroblasts expressed the VDR $\Delta$ K246 mutant protein but were unresponsive to 1,25(OH) $_2$ D. The  $\Delta$ K246 mutation abolished heterodimerization with RXR and binding to coactivators.

A Korean girl (F83) with HVDRR without alopecia was heterozygous for two VDR mutations [123]. The girl and her father were both heterozygous for a C-to-T mutation in exon 4 that changed a threonine to isoleucine at amino acid 146 (Thr146Ile). The girl and her mother were both heterozygous for C-to-T mutation in exon 5 that changed arginine to cysteine (Arg158Cys).

A Chinese boy (F106) with HVDRR without alopecia was heterozygous for two VDR mutations [126]. The boy and his mother were heterozygous for a mutation in exon 3 that changed arginine to glutamine at amino acid 80 (Arg80Gln). The patient was also heterozygous for an A to T base substitution in exon 7 that changed asparagine to tyrosine at amino acid 276 (Asn276Tyr). Interestingly, the father had no mutations in his VDR gene suggesting that the Asn276Tyr mutation arose spontaneously. The Arg80Gln mutation was previously found in three families all with origins in North Africa [75,102].

A Chinese girl (F88) with HVDRR without alopecia had a heterozygous C to G substitution in exon 6 that changed histidine to glutamine at amino acid 229 (His229Gln) [127]. The patient also was heterozygous for the Met1 and Met4 polymorphisms in the VDR translation start sites. Sequencing of the patient's VDR cDNA showed that the Met1 and Met4 start sites were both present on the allele that had the His229Gln mutation. This meant that the allele with the His229 wild-type sequence had the Met1 and Met4 polymorphisms that did not encode a start site. A potential downstream start site at Met40 would have deleted the first zinc finger of the DBD rendering this protein inactive. An Asian boy (F144) was found to have two heterozygous mutations in the VDR gene. One mutation changed a methionine to threonine at amino acid 52 (Met52Thr). The second mutation was a seven bp deletion (c.941-947delACCAAAG) that caused a frameshift (Thr301ProfsX6) that truncated the VDR [153].

## 5.6 Dominant negative mutations

A mutation in the Glu420 residue was found in a German girl (F86) with HVDRR without alopecia. In this case, glutamic acid was mutated to alanine (Glu420Ala) [125]. The girl and her father were heterozygous for the missense mutation while the mother had no mutations in the VDR gene. The girl's father showed minor symptoms of vitamin D resistance. Fibroblasts from the girl and her father showed resistance to 1,25(OH) $_2$ D $_3$ . The heterozygous Glu420Ala mutation appears to act in a dominant negative manner silencing the WT VDR in the girl and possibly also causing bone disease and resistance to vitamin D action in the father. This

was the first report of HVDRR caused by a heterozygous missense mutation.

A Japanese boy (F110) with short stature and bowlegs was shown to have an 8 base pair deletion (c.1239-1246delAGTACCGC) and an Arg370His substitution [34]. The Arg370His mutant VDR appeared to have no effect on transcriptional activity. The 8 base pair deletion resulted in a frameshift (p.Gln400LeufsX7) that deleted helix H12. The Gln400LeufsX7 truncated VDR was transcriptionally inactive but exhibited a dominant-negative effect on wild-type VDR in transactivation assays [34]. The boy's father who was heterozygous for the Gln400LeufsX7 mutation also had slight bowing of legs. A Hispanic female (F114) with HVDRR without alopecia was shown to be heterozygous for both Arg73Glu and Arg274His mutations [144].

### 5.7 Other mutations in the VDR

A young boy (F66) from Chile with HVDRR without alopecia was found to have a unique 5-bp deletion/8-bp insertion in exon 4 of the *VDR* gene [113]. The mutation in helix H1 of the LBD deleted His141 and Tyr142 and inserted three amino acids in their place (Leu141, Trp142, and Ala143). The patient's fibroblasts had no demonstrable [ $^3\text{H}$ ]1,25(OH) $_2$ D binding and were resistant to 1,25(OH) $_2$ D treatment. When the effects of the three individual mutations were analyzed separately, only the insertion of Ala143 into the WT VDR disrupted VDR transactivation to the same extent observed with the child's mutated VDR. A young Jamaican boy (F71) with HVDRR and patchy alopecia was found to have a 102 bp insertion/duplication in the *VDR* gene that introduced a premature stop (Tyr401stop) [116]. The mutation deleted a part of helix H11 and all of helix H12. The patient's fibroblasts expressed the truncated VDR but were resistant to 1,25(OH) $_2$ D. The truncated VDR weakly bound [ $^3\text{H}$ ]1,25(OH) $_2$ D and was able to heterodimerize with RXR, bind to DNA and interact with the corepressor hairless (HR). However, the truncated VDR failed to bind coactivators and was transactivation defective. A Turkish patient (F134) with HVDRR and alopecia was found to have a duplication of guanine (c.66dupG) in exon 2. The mutation causes a frameshift (p.Ile23AspfsX20) that truncates the VDR [150].

### 5.8 HVDRR in dogs and cats

There are several reports of HVDRR in pets. HVDRR was diagnosed in a Pomeranian dog [177]. On physical examination, the dog exhibited lateral bowing of the antebrachium of both forelimbs and generalized non-pruritic partial alopecia. Serum biochemistry revealed marked hypocalcemia and increased alkaline

phosphatase. Although her alopecia was resolving, the dog's coat was of poorer quality than that of her half-sibling. At 8 months of age, while receiving 1,25(OH) $_2$ D, the dog's serum calcium was very low (total calcium 5.4 mg/dL; normal 8.9–11.4 mg/dL) despite exceptionally high 25(OH)D levels (1017 pg/mL; normal 25–50 pg/mL) indicative of HVDRR. Analysis of the *VDR* gene revealed a single base deletion in exon 4 that led to a frameshift causing the amino acid sequence to diverge after Arg175. An additional 41 amino acids were in the frame before a downstream termination signal occurred. The mutation deleted a major part of the LBD and caused the VDR to be nonfunctional. The dog was eventually treated with intravenous (IV) calcium gluconate. After initial stabilization, a neurologic examination revealed signs attributable to diffuse forebrain disease and hindlimb paresis. Spinal radiographs and computed tomography confirmed a fracture of T11 and showed accompanying spinal cord compression. Flaring of the ribs at the costochondral junctions (so-called rachitic rosary in people) was also readily apparent on radiographs. Given the severity of the dog's spinal injury, the decision was made to euthanize the animal. This was the first molecular description of a mutation causing HVDRR in a mammal other than humans.

Two cats reported earlier had the classic picture of HVDRR but any *VDR* mutations were not described. In one report, a 4-month-old male domestic shorthair cat was examined because of lethargy, vomiting, diarrhea, muscle tremors, and mydriasis. Laboratory evaluation revealed hypocalcemia, hypophosphatemia, and high serum 1,25(OH) $_2$ D and PTH levels. The cat was treated with oral calcium and calcitriol supplements. After 18 months of treatment, the cat was clinically normal. After the treatment was discontinued, the cat was able to maintain normal serum calcium levels [178]. This is reminiscent of some HVDRR patients after puberty.

A second report described the biochemical abnormalities and radiographic changes in a 4-month-old kitten with symptoms of HVDRR [179]. The kitten was treated with calcium and vitamin D. The treatment failed to increase the serum calcium levels or reverse the lateral antebrachial bowing, lumbar spinal lordosis and costochondral beading. The cat was euthanized at 9 years of age as a result of refractory hip pain [180].

### 5.9 HVDRR without mutations in the VDR

Since the initial description of HVDRR as a genetic disorder, mutations in the *VDR* gene were suspected as the likely cause of 1,25(OH) $_2$ D resistance. Although the *VDR* is the principal determinant of the 1,25(OH) $_2$ D action pathway, it is possible that target

organ resistance to  $1,25(\text{OH})_2\text{D}$  may result from mutations in other proteins that are essential to the transactivation process.

Hewison et al. [16] have described a case of HVDRR in which a mutation could not be found in the VDR. The patient (F48), a young girl of English descent, exhibited all of the hallmarks of HVDRR including alopecia. The patient's fibroblasts expressed a normal-sized VDR mRNA and exhibited normal  $[^3\text{H}]1,25(\text{OH})_2\text{D}$  binding. However, no induction of 24-hydroxylase activity was observed when the fibroblasts were treated with up to  $1\ \mu\text{M}$   $1,25(\text{OH})_2\text{D}$ . The patient's VDR mRNA was reverse-transcribed and amplified by PCR however, no mutations were found in the VDR cDNA. In transactivation assays, the patient's VDR cDNA exhibited a normal transactivation response to  $1,25(\text{OH})_2\text{D}$  in CV-1 cells. These results indicated that the patient's VDR DNA sequence was normal and functional. The authors suggested that the tissue resistance was not due to a defect in the VDR and that the hormone resistance causing HVDRR was most likely the result of a mutation in an essential protein that participates in the  $1,25(\text{OH})_2\text{D}$  action pathway.

In a follow-up study of this interesting case, Chen et al. [17] proposed that the cause of  $1,25(\text{OH})_2\text{D}_3$  resistance was due to the abnormal expression of a VDRE-interacting hormone response element-binding protein. This protein is a member of the heterogeneous nuclear ribonucleoprotein (hnRNP) family that binds to double-stranded DNA and modulates RNA processing. This mechanism has led to designating this type of rickets in the category of VDDR-2B along with HVDRR (VDDR-2A) as pathways that block  $1,25(\text{OH})_2\text{D}$  action. The authors proposed that this case of vitamin D resistance in a human subject is similar to that previously described for New World primates in which abnormal expression of a hormone response element-binding proteins can cause target cell resistance to  $1,25(\text{OH})_2\text{D}$  and also to estrogens [17,181]. That this protein is a member of the hnRNP family capable of interacting with double-stranded DNA highlights a potentially important new component of the complex machinery required for steroid hormone signal transduction.

In Cauca, Columbia, more than 200 patients were diagnosed with a disease that somewhat resembles HVDRR without alopecia [182]. The patients exhibit lower limb deformities due to rickets but were otherwise in good physical condition. Rickets limited to the lower extremities, as in these cases, has not been reported in other HVDRR families. The affected individuals had serum calcium levels that were within the normal range but their serum  $1,25(\text{OH})_2\text{D}$  levels were unusually high suggesting target-organ resistance. Fibroblasts from two of the most severely affected patients showed reduced

induction of 24-hydroxylase activity by  $1,25(\text{OH})_2\text{D}$ . However, no mutations were found in the VDR gene. Since the cause of vitamin D resistance in this instance was not due to mutations in the VDR and functional response to  $1,25(\text{OH})_2\text{D}$  was demonstrated, it has not been clearly ascertained whether this entity is a variant of HVDRR or not. The high prevalence of the unique disease in the population and the localized distribution of rickets raise the possibility of an environmental cause. These cases support the concept that targets organ resistance to  $1,25(\text{OH})_2\text{D}$  may be due to mechanisms other than mutations in the VDR or overexpression of components such as an hnRNP that can inhibit  $1,25(\text{OH})_2\text{D}$  signaling.

## 6. Therapy of HVDRR (VDDR-2) patients

### 6.1 Vitamin D

Mutations in the VDR that cause HVDRR reduce calcium and phosphate absorption from the intestine and result in hypocalcemia. The low levels of serum calcium lead to secondary hyperparathyroidism that contributes to the developing hypophosphatemia and to a decrease in bone mineralization that causes rickets. Although endogenous  $1,25(\text{OH})_2\text{D}$  is already elevated, early attempts at therapy focused on the administration of high doses of vitamin D or more active metabolites, the responses have varied widely. From these early studies, it appeared that patients with HVDRR without alopecia responded better to treatment with vitamin D preparations than patients with alopecia [39]. Some patients without alopecia showed improvement both clinically and radiologically after the administration of pharmacological doses of vitamin D ranging from 5000 to 40,000 IU/day [20,21,68]; or 20–200  $\mu\text{g}/\text{day}$  of  $25(\text{OH})\text{D}_3$  or 17–20  $\mu\text{g}/\text{day}$  of  $1,25(\text{OH})_2\text{D}_3$  [21]. One patient (F51) with HVDRR without alopecia with the His305Gln mutation, a contact point for the 25-hydroxyl group of  $1,25(\text{OH})_2\text{D}_3$ , responded to 12.5  $\mu\text{g}/\text{day}$  calcitriol [104,105]. The treatment overcame the low affinity-binding defect and achieved adequate VDR occupancy to mediate normal  $1,25(\text{OH})_2\text{D}_3$  responses. Patient (F4) with the Ile314Ser mutation in the VDR LBD was treated with 1 mg/day of vitamin  $\text{D}_2$  from age 2 to age 18 [68]. At age 20 following an uneventful pregnancy, the patient developed hypocalcemia and was treated successfully with 50  $\mu\text{g}/\text{day}$  of  $25(\text{OH})\text{D}_3$ . On the other hand, the patient (F21) with the Arg274Leu mutation in the VDR LBD, a contact point for the  $1\alpha$ -hydroxyl group of  $1,25(\text{OH})_2\text{D}_3$ , failed to respond to treatment with huge doses of vitamin D or its more active metabolites: 600,000 IU vitamin D; or up to 24  $\mu\text{g}/\text{day}$  of  $1,25(\text{OH})_2\text{D}_3$  (calcitriol); or 12  $\mu\text{g}/\text{day}$   $1\alpha$ -(OH) $\text{D}_3$ . The patient later died of pneumonia [31].

Although HVDRR patients with alopecia appeared to be more resistant to treatment with vitamin D metabolites, some of these patients were treated successfully using vitamin D. Two patients (F6, F10) showed signs of improvement when given vitamin D or  $1\alpha$ -(OH) $D_3$  [77,81] and one patient (F15) responded to 25(OH) $D$  as well as  $1\alpha$ -OHD $_3$  [28]. Both  $1\alpha$ -OHD $_3$  and 1,25(OH) $_2D_3$  were also effective treatments in other cases [63,76,79,91,95] including patients (F26, F19) with the Arg50Gln and Arg73Gln mutations [49,65]. Two siblings (F32), with the Glu152stop mutation, showed no increase in serum calcium during high-dose vitamin D treatment despite raising their circulating 1,25(OH) $_2D$  levels to more than 100 times the mean normal range. However, notwithstanding their low serum calcium concentrations, healing of rickets and suppression of PTH were evident [94]. In one case (F3), where vitamin D and 1,25(OH) $_2D$  therapies failed, the patient responded to oral phosphorous treatment [26]. In many cases when patients fail to respond to 1,25(OH) $_2D$ , intensive calcium therapy is used as described below. Since many cases have limited or no response to vitamin D, many patients are now being initially treated with calcium saving time and effort with vitamin D therapy that often fails.

## 6.2 Calcium

Balsan et al. [183], Weisman et al. [184], and Bliziotis et al. [30] early on reported the most significant development in the treatment of HVDRR at the time. In their early studies, they used long-term IV calcium infusions to successfully treat patients with HVDRR who had failed prior treatments with large doses of vitamin D derivatives and/or oral calcium. This novel therapy bypassed the calcium absorption defect in the intestine caused by the mutant VDR. The patient in the Balsan study was infused with high IV doses of calcium during the nocturnal hours over 9 months. Clinical improvement including relief of bone pain was observed within the first 2 weeks of therapy. Within 7 months, the child gained both weight and height. Eventually, the serum calcium normalized, the secondary hyperparathyroidism was reversed, and rickets ultimately resolved as assessed by X-ray and bone biopsy. However, when the IV infusions were discontinued the hypocalcemia and rickets returned [183].

In the Weisman study, two boys aged six and four (F24, F28) with HVDRR, rickets, alopecia, and growth retardation failed to respond to pharmacologic doses of vitamin D or its active metabolites. The boys were then treated with long-term intracaval infusions of calcium through an implantable catheter. A total of 0.5–0.9 g of elemental calcium was infused daily for

18 months and the serum calcium concentration was maintained at 9–10 mg/dL. Bone pain subsided within 1 week of treatment. Serum phosphorus, PTH, 1,25(OH) $_2D$ , and alkaline phosphatase activity were normalized within 4–9 months. Radiographs of the knees and hands showed healing of rickets with complete resolution after 1 year of treatment. The boys grew 12 and 8 cm per year in height. A transilial bone biopsy obtained from one child prior to treatment revealed severe osteomalacia associated with osteitis fibrosa. A follow-up biopsy examined after 12 months of therapy showed almost complete healing of osteomalacia and normal mineralization. Thus long-term intracaval calcium infusions are an effective mode of therapy for HVDRR patients, and when normal serum calcium and phosphorus concentrations are maintained, healing of rickets and normal growth rate could be achieved even in the absence of a functional VDR [184].

In the Bliziotis et al. study [30] unidirectional intestinal fractional calcium absorption (FCA) was measured with stable calcium isotopes in a patient with HVDRR, before the patient was treated with any calciferol. FCA was reduced at 14% (normal, 20%–70%), and no increase in calcium absorption was seen when serum 1,25(OH) $_2D$  levels were more than 50-fold elevated. The patients's cultured skin fibroblasts contained no detectable 24-hydroxylase activity in response to high doses of 1,25(OH) $_2D$ . High-dose IV calcium infusions and oral phosphorus supplementation for 135 days improved or normalized biochemical parameters and resulted in radiographic healing of the rachitic lesions.

Several other groups reported using IV calcium infusions as a therapy for HVDRR. Hochberg et al. [185] reported that in some cases, after radiological healing of the rickets has been achieved with IV calcium infusions, switching to high-dose oral calcium therapy was effective in maintaining normal serum calcium concentrations.

Much of the following description is based on the experience with the Israeli cohort of HVDRR cases (and one of the co-authors of this chapter, D.T.) [186]. This cohort is composed of a group of 28 patients, most with defined VDR mutations, that have been followed for many years. The experience to be described has been gleaned from patients belonging to four families, each family with a different mutation. The patients currently range from newborn to ~36 years of age. Their phenotypes and genotypes have been previously described [25,187]. One family (F11) has a Tyr295stop nonsense mutation in the LBD that truncates the VDR rendering it devoid of biological function [33,62]. Two families have missense mutations in VDR DBD. In one family (F31), a Gly33Asp mutation was identified near the tip of the first zinc finger [65,93]. In the other family (F49), an Arg80Gln mutation was identified in the base

of the second zinc finger [102]. In the fourth family (F24), the patient's cultured skin fibroblasts failed to bind [ $^3\text{H}$ ] 1,25(OH) $_2$ D, and 1,25(OH) $_2$ D treatment failed to stimulate 24-hydroxylase activity. Molecular analysis of the VDR defect was not performed in this patient [185,188]. Other investigators [130,189], shared their experience that in children beyond infancy presenting with severe rickets and bone deformities, the most reliably effective therapeutic measure is long-term IV calcium infusion to heal the "hungry bones". The infusions usually require establishing a central IV port to allow continuous infusions over prolonged periods. In the hands of the Israeli group, the following plan has proved successful. The initial infusion solution of 100 mg of elemental calcium (calcium gluconogalactogluconate) in 500 mL isotonic sodium chloride is increased gradually to doses of 500–1000 mg of elemental calcium. The infusion is administered continuously, 24 h daily during the first month, and gradually reduced to 12 h daily given overnight. The dosage must be adjusted frequently to avoid severe hypercalciuria i.e., keeping the ratio of urine calcium to urine creatinine less than 3 (Ucal/Ucrea <0.3), and to achieve a serum calcium concentration of 2.1–2.5 mmol/L (8.4–10 mg/dL). Cardiac monitoring is important to prevent bradycardia. Clinical improvement is expected within a week of starting intravenous (IV) therapy, at which time bone pain recedes. Some young patients started to walk for the first time within a week of starting IV therapy. Once the "hungry bones" are corrected, transition to therapy with high-dose oral calcium can be successful and is recommended. The group advises a large oral dose of 5–6 g per meter square body surface of elemental calcium. This dose has been shown to be required for some patients to maintain normal calcium and phosphorus levels, thus preventing rickets and promoting normal linear growth. The detailed use of IV calcium with varying protocols in the pediatric population has also been reported by Malloy et al. [23], Forghani et al. [24], and Ma et al. [117].

Delivery of calcium through a central vein, over an extended period of time started in hospital but continued at home, has been associated with significant morbidity. During the initial week of therapy, cardiac arrhythmias, mostly bradycardia, have been observed. Reduction in the infusion rate has been shown to eliminate the bradycardia. Episodes of septicemia occur frequently and require hospitalization, cessation of calcium therapy, removal of the central catheter, and IV antibiotics [23]. Whether this problem is due to decreased ability of HVDRR patients to fight infection or is a problem inherent with long-term IV infusions, especially in the home setting, is not clear [23]. For example, in a case of an infant (F94) with a Leu227Pro mutation, the child developed repeated IV infections in the

intravenous line used to provide calcium [130]. The infant could not be adequately maintained with oral calcium and the investigators felt it necessary to remove the IV line to avoid septicemia. In this case, the clinicians were able to maintain calcium levels above 8 mg/dL using the intravenous preparation of calcium chloride administered via gastric tube [130]. Another example of avoiding a central port was presented by Abali et al. [150] who reported success with IV calcium administered intermittently via a peripheral route in 4 HVDRR children aged 1.5–9.8 years. They reported no complications such as infection, extravasation, or arrhythmias with peripheral infusion over 1–22 months. The treatment normalized PTH and alkaline phosphatase in all patients, after which, oral Ca of 200–400 mg/kg/day and calcitriol of 0.5  $\mu\text{g/kg/day}$  were sufficient to maintain normal PTH levels.

After IV or another mode of calcium delivery normalizes rickets and metabolic abnormalities, the patients can often be switched to oral calcium. Many patients can be maintained on oral calcium thereafter; however, occasionally some patients fall back to hypocalcemia due to decreased compliance or lack of tolerance to the high doses of calcium. IV calcium therapy could then re-instituted.

Several groups [117,135,185,190] have subsequently found that oral calcium in high doses may be successful as initial therapy or follow-up therapy after IV calcium. Initial oral therapy may allow avoidance of ever requiring IV calcium therapy. The dose required is approximately 5–6 g per meter square body surface of elemental calcium but other studies have had success with lower doses. If successful in restoring normocalcemia and reversing secondary hyperparathyroidism, IV infusions with all of their associated problems may be avoided. On the other hand, if the patient has required IV calcium to replenish calcium deficits, a transition to oral calcium should be attempted. For example, in a study by Sakati et al. [88], a patient (F23) who failed to respond to calciferol received 3–4 g of elemental calcium orally per day and showed clinical improvement during 4 months of therapy. The patient cells were later shown to be totally resistant to 1,25(OH) $_2$ D due to a Gly46Asp mutation in the VDR DBD [87].

### 6.3 Cinacalcet

Another adjunctive therapeutic approach to treating the mineral abnormalities in HVDRR is the addition of Cinacalcet to inhibit the secondary hyperparathyroidism as initially suggested by Srivastava and Alon [191]. Secondary hyperparathyroidism from inadequate calcium absorption in the gut as well as lack of PTH suppression by 1,25(OH) $_2$ D and increased excretion of

phosphate, contributes to the underlying pathophysiology for rachitic changes in HVDRR. Srivastava and Alon used Cinacalcet to treat a child with HVDRR in whom conventional modes of IV calcium therapy had to be discontinued. Cinacalcet therapy together with high-dose oral calcium effectively normalized the metabolic abnormalities and the rachitic bone condition. The authors suggested that the relative ease of administration of the calcimimetic as a once- or twice-daily oral preparation, compared with traditional intravenous calcium administration, should encourage its move to the frontline of combination treatment of the acute phase of HVDRR. Others have since reported on the successful addition of Cinacalcet to their treatment regimen [143,148,153,192]. If successful, the addition of Cinacalcet to high-dose oral calcium may allow avoidance of requiring intensive IV calcium with all of its attendant problems.

#### 6.4 Prenatal diagnosis

In affected families, HVDRR can be diagnosed during pregnancy by chorionic villus sampling (CVS) or amniocentesis. In some cases defects in the unborn child's VDR have been detected using [ $^3\text{H}$ ]1,25(OH) $_2$ D-binding assays and 1,25(OH) $_2$ D-induction of 24-hydroxylase activity in cultured cells obtained from CVS or amniotic fluid [188]. In other cases, a prenatal diagnosis of HVDRR was determined by examining DNA from chorionic villus samples for RFLPs generated by known mutations in the VDR gene [193]. Early diagnosis prompts timely treatment soon after birth before bones become undermineralized and severe rickets develops.

#### 6.5 Future therapy using rationally designed vitamin D analogs

Vitamin D analogs have been proposed as a potential therapy for patients with HVDRR especially those with mutations in the VDR LBD [194–198]. The use of vitamin D analogs is based on the rationale that they bind to the VDR at different amino acid contact points than 1,25(OH) $_2$ D. Using cultured fibroblasts from patients and in vitro transactivation assays, the vitamin D analogs 20-epi-1,25(OH) $_2$ D and 1 $\beta$ -hydroxymethyl-3-epi-16-ene-26 $\alpha$ ,27 $\alpha$ -bishomo-25(OH)D were shown to partially or completely restore the responsiveness to the Arg274Leu and His305Gln mutant VDRs but were less effective in activating the Ph2251Cys mutant [194]. These results suggest that mutations that are involved in ligand binding rather than those that are involved in heterodimerization or coactivator binding are more likely to respond to analogs. Future therapy using

vitamin D analogs could be based on a rationale drug design for individual patients with specific types of VDR mutations. However, we realize that the economic feasibility of this approach may be excessive for any individual patient.

### 7. Hypothesis regarding the mechanism for spontaneous healing: outgrowing the need for substantial calcium supplementation in many HVDRR patients after puberty

#### 7.1 Spontaneous healing

An interesting dilemma regarding HVDRR is that multiple patients have had a spontaneous improvement in their rickets but not their alopecia [37,63,64,128]. Spontaneous healing of rickets usually happens between 7 and 15 years of age and was often associated with the time of puberty. See next Section 7.2 below for a hypothesis to explain this effect at puberty. Sometimes the spontaneous recovery occurs after the patient has undergone a relatively ineffective long-term treatment with vitamin D metabolites and mineral replacement. The healing process arises spontaneously and does not appear to be related to the treatment. In some patients, spontaneous improvement occurred after treatment was discontinued [63]. The patients appear to remain eucalcemic with reduced or without calcium supplements and show no evidence of osteomalacia or rickets. Interestingly, cultured fibroblasts obtained from a skin biopsy of a patient taken after spontaneous healing of rickets had occurred were still resistant to 1,25(OH) $_2$ D [63]. Spontaneous improvement has been observed in patients (F18) [37,64] with the Tyr295stop mutation [66,102] and in patients (F19) [63] with the Arg73Gln mutation [65]. Despite the patient's improvement in their hypocalcemia and rickets, the alopecia remained [37,63,64]. It is not clear from the published studies whether this phenomenon of spontaneous improvement with age also occurs in the genetic rickets patients caused by mutations in the *CYP2R1* and *CYP27B1* (VDDR-1) genes. In these cases, where there are active vitamin D molecules that can treat the disease by bypassing the enzymatic defect, there has been less study of spontaneous improvement, although some anecdotal cases of improvement with age have been noted by investigators who care for these cases [199,200]. See Chapters 66 and 67 for a full discussion of VDDR-1 entities.

#### 7.2 Studies of calcium absorption and puberty

As discussed above, during the time surrounding puberty and into young adulthood, many but not all

HVDRR patients are able to maintain normal serum calcium levels with more modest oral calcium supplements or, in some cases, even without supplements. Many patient's overt metabolic abnormalities shift toward exhibiting near-normal PTH levels with normal bone mineral density, although they continue to show elevated serum  $1,25(\text{OH})_2\text{D}$  levels, suggesting residual target organ resistance. The alopecia does not improve, again suggesting it is caused by a separate defect, due to mutated unliganded VDR and not vitamin D deficiency or resistance per se. In an attempt to understand the recovery phenomena, Tiosano et al. [201] studied calcium absorption in 17 HVDRR patients 1.5–37 years and age matched controls at different ages and found that they had a unique profile of intestinal calcium absorption and bone mineral accretion (Fig. 68.6). Fractional calcium absorption (FCA) and bone calcium accretion ( $\text{Vo}+$ ) were determined by stable-calcium isotopes. BMD was determined by dual-energy X-ray absorptiometry and bone structure by high-resolution magnetic resonance imaging.

FCA in the HVDRR patients was reduced under a low calcium diet from early childhood until the end of puberty compared to normal age-matched controls. However, from the end of puberty to ~28 years of age and possibly much longer, the HVDRR patients displayed a unique adaptation to low calcium intake, with a significant increase in calcium absorption that reached levels even higher than those of normal controls (Fig. 68.6). Bone calcium accretion was also higher in HVDRR patients compared to normal controls from infancy to adulthood, but not during early puberty [201]. As for

bone mineral density (BMD), although bone calcium accretion was higher in HVDRR patients than in controls, femoral neck BMD was significantly lower in patients aged 12–17 years than in patients older than 18 years, while their lumbar spine BMD was normal. The discrepancy between the high bone calcium accretion and the low femoral neck BMD in the younger group may be explained by their high PTH levels. In contrast, the combined significant increase in FCA accompanied by the decline in PTH levels and the presence of sex hormones after puberty appeared to contribute to the normalization of BMD postpuberty. Further investigation of the bone architecture by high-resolution MRI did not demonstrate any significant differences in cortical bone fraction, trabecular bone fraction, trabecular number, trabecular thickness, or trabecular separation between HVDRR patients and controls [201]. It appears, therefore, that adequate calcium supply and not the presence of functional VDR in human bone is critically important for bone development and mineralization, although impairments of bone quality and subclinical abnormalities not detectable by BMD and MRI studies cannot be excluded in HVDRR patients. This subject is extensively reviewed by Goltzman et al. [202] in mouse VDR knock-down models where they have carefully studied bone biopsies and concluded that calcium cannot entirely substitute for vitamin D in skeletal and mineral homeostasis in mice but that the two agents have discrete and overlapping functions (see Chapter 30 for more discussion).

Previous studies have demonstrated that estrogens regulate a vitamin D-independent pathway

**FIGURE 68.6 Fractional calcium absorption (FCA) in HVDRR patients and normal controls.** Line (a) (open triangles) represent FCA in normal age-matched control subjects at different ages on a low calcium diet. Line (b) (open diamonds) represents FCA in the HVDRR patients during a high calcium diet. Line (c) (black squares) represents FCA in the same HVDRR patients during a low-calcium diet. Line (c1) are children less than 17 years of age, line (c2) postpuberty ages 18 to 29 and line (c3) are HVDRR subjects older than 30 years. FCA in HVDRR patients aged 18–26 years (line c2) was significantly higher during low calcium intake than in patients younger than 17 years (line c1) and in those older than 29 years (line c3). There were no significant and consistent differences in FCA while on a high calcium intake before and after the end of puberty. The figure is used with permission from [201].

controlling calcium absorption, which likely is the mechanism for the improvement in calcium metabolism coincident with puberty [203–206]. Once the affected children pass through puberty, there is no difference between HVDRR in males and females, neither require high doses of calcium. Some can do well with only 0.5 g/day and some don't need any supplementation [186]. This phenomenon may be explained by the observation that in VDRKO mice intestinal calcium transporter genes are upregulated by estrogens through vitamin D and also VDR-independent mechanisms [203–207]. These studies demonstrated that estrogens regulate a vitamin D-independent pathway controlling calcium absorption, in mice and human cells. Furthermore, Nie et al. [206] showed duodenal calcium absorption in ovariectomized mice was significantly decreased, compared with control female mice, which returned to control level after 17 $\beta$ -estradiol replacement treatment. Estrogen regulated the expressions of TRPV6 and PMCA1b in murine and human duodenal mucosae and SCBN cells (human duodenal epithelial cells). The results from SCBN cells showed that 17 $\beta$ -estradiol regulated calcium influx through the effects of estrogen receptor (ER)  $\alpha$  and  $\beta$  on TRPV6 and PMCA1b, respectively [206].

In boys, it appears to be the same mechanism that overcomes the need for supplementation as in girls, a vitamin D independent pathway mediated by estrogens. The levels of testosterone in the blood are 1000-fold higher than the estrogens in boys. High levels of the CYP19 enzyme (aromatase) immunoreactivity were detected within human gastric glands irrespective of age or sex [208]. These results suggest that human parietal cells synthesize estrogens from androgen precursors within gastric mucosa and subsequently secrete them into the portal vein for systemic effects via a gastric vein or perhaps also directly flow into the lumen and down the GI tract.

Once the testosterone level is high enough at puberty in boys, it can be converted to estrogen in the GI tract to enhance the local expression of calcium transporters [208]. Estrogens and vitamin D are thus independent potent regulators of the expression of the calcium influx channels TRPV6 and PMCA1b [206], which are involved in active intestinal calcium absorption. Estrogens and prolactin have also been shown during pregnancy or lactation to have distinct, vitamin D-independent effects at the genomic level on active duodenal calcium absorption mechanisms [207], so multiple factors acting independently of the VDR may be playing a role at different times depending on the physiological situation.

Studies on this hypothesis in HVDRR patients are continuing in order to gain further evidence to support the theory that estrogens are the mechanism for the

phenomenon of HVDRR patients no longer requiring high-dose calcium supplements after puberty. Also, in cases of VDDR-1A and 1B vitamin D deficiency due to synthetic enzyme mutations, there may be some evidence developing that a similar improvement in bone status occurs in adults [199,200]. As seen in Fig. 68.6, in HVDRR patients the FCA rises between age 15 and 30 but seems to fall again after age  $\sim$ 30. This fall in FCA will be the focus of future study. It will be of great interest to follow the status of the calcium levels and bone density in HVDRR adults as they age and the women cross menopause.

## 8. Alopecia

### 8.1 HVDRR (VDDR-2A) and alopecia

The main unresolved medical problem of some HVDRR patients is persistent alopecia despite normalization of both serum biochemistry assays and rickets. The number of hair follicles seems to be normal. However, hair does not grow during childhood and the hair follicles are empty. In some cases papular lesions develop on the face and shoulders, but usually not on the scalp. Both the clinical presentation and the hair histology are similar to those found in the autosomal recessive disease total alopecia known as "atrachia with papular lesions" [209–211] due to mutations in the *hr* gene [212]. The alopecia is socially troublesome and is sometimes made more acceptable using a wig, but normalization of calcium does not improve the alopecia in those that have it.

The mechanism of how the VDR regulates hair growth is still being completely elucidated but efforts from the Demay group and others [213] are providing insight into the mechanism behind the linkage to vitamin D and the VDR which is discussed in Chapter 25. Understanding gained from the molecular analysis of the VDR from HVDRR patients with and without alopecia along with studies in VDR knockout mice (Chapter 30) has revealed a number of interesting findings concerning the role of the VDR and vitamin D in regulating hair growth. First, alopecia is not found in other patients with a genetic deficiency from birth including CYP27B1 mutations (VDDR-1A), CYP2R1 mutations (VDDR-1B), gain of function mutations in CYP3A4 (VDDR-3) or other forms of vitamin D deficiency including severe nutritional deficiency. In the *Cyp27b1* knockout mouse model, abnormalities develop in skeletal, reproductive, and immune function [214]. However, the *Cyp27b1* knockout mice do not develop alopecia. These findings indicate that 1,25(OH) $_2$ D itself is not required for hair development.

Studies of the mutations in HVDRR patients have revealed several interesting findings about the

mechanism of alopecia. HVDRR patients with VDR mutations in the DBD or with premature stop mutations all had alopecia. The alopecia remained unchanged in patients after successful therapy of hypocalcemia and in patients that showed spontaneous improvement in rickets with or without calcium supplementation. Alopecia was also present in patients with mutations that affect RXR $\alpha$ -heterodimerization (i.e., Phe251Cys, Gln259Pro and Arg391Cys). On the other hand, patients with mutations that affect ligand binding (i.e., Arg274Leu, His305Gln, Ile314Ser, and Trp286Arg) did not have alopecia.

Perhaps the most interesting case was a patient (F60) with the Glu420Lys mutation in helix H12 [32]. The Glu420Lys mutation had no effects on ligand binding or RXR heterodimerization but blocked coactivator interactions. However, this patient did not have alopecia and was resistant to even high doses of the hormone. Disruption of coactivator interactions is also implicated in the case of F118 with an Arg343His mutation described above, however, the patient did have alopecia [146]. A second patient with an Arg343Cys mutation also had alopecia [129]. Arg343 is located in helix H9 that is important in RXR heterodimerization but no defect was found in RXR heterodimerization in the Arg343His mutant VDR. Transactivation of the Arg343His mutant VDR was not rescued by the addition of the coactivator GRIP-1 suggesting a defect in coactivator interaction. Modeling shows that the Arg343His mutation blocks the interaction between Arg343 and Gln259 in helix H5 and alters the formation of the cleft needed for coactivator binding [146]. These findings suggest that mutations that affect helix H5 and H12 have differential effects on alopecia even though they both appear to affect coactivator interactions.

Additional evidence supporting these findings include studies in VDR knockout mice that showed that these mice develop alopecia despite calcium supplementation that maintains calcium levels and prevents rickets, indicating that the intact VDR itself (unliganded) is essential for hair growth [215,216]. Also, targeting WT VDR to keratinocytes in *Vdr* knockout mice prevents alopecia [217]. Importantly, when ligand-binding defective or coactivator-binding defective mutant VDRs were specifically expressed in keratinocytes in *Vdr* knockout mice with alopecia, hair growth was fully or partially restored [47]. A role for RXR in hair growth is clearly established as targeted inactivation of RXR $\alpha$  in keratinocytes also causes alopecia [218].

The alopecia associated with HVDRR is clinically and pathologically indistinguishable from the generalized atrichia with papules found in patients with mutations in the *hr* gene [43,44,219,220]. The *hr* gene is expressed in many tissues especially in the skin and brain [221]. The *hr* gene product, HR, acts as a

corepressor and directly interacts with the VDR, and suppresses 1,25(OH) $_2$ D-mediated transactivation [222–224]. Like the VDR, HR is a zinc finger protein suggesting that it interacts with DNA. It has been hypothesized that the role of the VDR in the hair cycle is to repress the expression of a gene(s) in a ligand-independent manner [5,10,32,47,113,222,224]. The ligand-independent activity requires that the VDR heterodimerize with RXR and bind to DNA even if it failed to activate gene transcription [5,32]. The corepressor actions of HR may also be required in order for the unliganded VDR to repress gene transcription during the hair cycle. Mutations in the VDR that disrupt the ability of the unliganded VDR to suppress gene transcription are hypothesized to lead to the derepression of a gene(s) whose product, when expressed inappropriately, disrupts the hair cycle that ultimately leads to alopecia [5,10,47,113,222,224].

RNA-Seq studies by Saini et al. [213] found that >80% of differentially expressed genes were upregulated in keratinocyte stem cells (KSC) from *Vdr* knockout mice demonstrating that the VDR suppresses transcription in WT-KSCs. Among the genes that were upregulated, PPAR $\gamma$ , a major regulator of adipogenesis, emerged as a candidate for further study. The authors showed that the VDR was recruited to the regulatory region of PPAR $\gamma$  gene. Furthermore, they demonstrated that preventing PPAR $\gamma$  overexpression restores hair regrowth. Supporting evidence for the actions of unliganded VDR was presented by Lee and Pike [225] comparing *Vdr* null and *Cyp27b1* null mice concluding that the VDR may function as a selective suppressor/derepressor of gene expression in the absence of 1,25(OH) $_2$ D. See Chapter 25 for further discussion.

## 9. Extra-skeletal actions of vitamin D in HVDRR (VDDR-2A) patients

### 9.1 Extra-skeletal aspects of HVDRR

As mentioned above and discussed extensively in many chapters in this volume, in addition to maintaining calcium homeostasis, 1,25(OH) $_2$ D has been shown to regulate multiple nonskeletal biological processes in many tissues and malignancies including the immune system [226–235]. Expression of *VDR* and *CYP27B1* has been found in many tissues and cancers that have been tested and evidence of functional responses in all these diverse parts of the body including cancer and the immune system are now commonplace [226–235]. The *Vdr* knockout mouse model has been used to analyze the abnormalities caused by the loss of VDR action in detail not possible in HVDRR patients (see Chapter 30).

The clinical findings in a limited number of children and young adults who constitute what we refer to as the Israeli Cohort have been followed medically for years [186] and will be further discussed below in the following sections. Although there are many pleiotropic tissue responses regulated by  $1,25(\text{OH})_2\text{D}$ , children and young adults with HVDRR appear relatively normal except for the constellation of features that relate to their calcium deficiency, rickets, secondary hyper-parathyroidism and alopecia if present. The entire cohort of 26 HVDRR patients from delivery to 46 years of age maintains a normal lifestyle. They exhibit none of the diseases being studied for increased risk or worse prognosis in vitamin D deficiency including cancer, autoimmune disease, cardiovascular disease, diabetes, and others. The married men and women have normal pregnancies and healthy babies delivered at term. They take no medications except some take modest calcium supplements.

## 9.2 The immune system in HVDRR patients

VDRs have been found in hematolymphopoietic cells and  $1,25(\text{OH})_2\text{D}$  has been shown to regulate cell differentiation and the production of interleukins and cytokines [226,235] (see several chapters in Section 11 of this book). Neutrophils isolated from HVDRR patients exhibit only minor aberrations in their fungicidal activity [236], and HVDRR patients have no clinically apparent immunologic defects. Tiosano et al. [237] studied the monocytes of HVDRR patients and found that activating toll-like receptors (TLRs) in the presence of vitamin D initiated a cascade that enhanced *VDR*, *CYP27B1*, and *hnrNP* expression and down-regulated *TLR2* expression.

During the COVID-19 pandemic, among 36 Israeli HVDRR patients, two were found to be positive for SARS-CoV-2 and they had very mild disease. In line with this observation, an HVDRR patient with a DBD mutation and her heterozygotic parents all had mild COVID illness [152,238]. The R80W mutation present in the affected child is located in the C terminal part of the second zinc finger in the DBD of the VDR. Although all family members generated comparable levels of IgG antibodies against the receptor binding domain of the SARS-CoV-2 spike protein as seen in COVID-19 convalescent serum in the general population, their T-cell responses were decreased. Interestingly although the heterozygous family members did not exhibit any signs of HVDRR, their T-cell responses were reduced by 50% commensurate with the percent of wild-type VDR present [152]. Vitamin D and the COVID-19 pandemic are discussed in more detail in Chapter 100.

## 9.3 Autoimmune disease and cancer

Autoimmune diseases, characterized by an inflammatory autoimmune response against self, are the third

leading cause of morbidity in the industrialized world and a leading cause of mortality among women [235]. Autoimmune diseases are chronic conditions with increasing prevalence with age. In a substudy of data from the large VITAL trial that included 25,871 participants, consisting of men  $\geq 50$  years and women  $\geq 55$  years at enrollment, vitamin D supplements were given for 5 years, with or without omega 3 fatty acids. Vitamin D supplementation reduced autoimmune disease by 22%, while omega 3 fatty acid supplementation with or without vitamin D, the reduction was not statistically significant. So although these subjects did not have HVDRR, the importance of the finding was to demonstrate that vitamin D regulates a wide array of genes involved in inflammation and immunity. This study of more than 25,000 older adults in the US provides evidence that daily supplementation with 2000 IU/day of vitamin D or a combination of vitamin D and omega 3 fatty acids for 5 years reduced autoimmune disease incidence. The clinical importance of these findings is high and the results were positive across different autoimmune diseases and demonstrated increasing benefits with time [235]. Whether the HVDRR subjects will show increased problems with autoimmune disease as they age will of course be carefully watched. Vitamin D effects on various autoimmune diseases are discussed in several chapters in Section 11 of this book.

Similar benefits in improving survival in cancer patient were also reported from a reanalysis of the VITAL trial. In the follow-up analysis [239], that accounted for cancer latency by excluding the first year or first 2 years of follow-up, the improvements in survival were statistically significant and as high as 22% and 25% improvement respectively. The authors concluded that updated meta-analyses of randomized controlled trials that include VITAL and other recent vitamin D randomized controlled trials indicate a significant reduction in cancer mortality but not in cancer incidence or cardiovascular disease endpoints [240]. The effects of vitamin D on cancer are discussed in multiple chapters in Section 10 of this book. So the question is whether the HVDRR-affected individuals will lose the protection offered by vitamin D activity protecting against cancer and autoimmune disease as they grow older or will other Vitamin D-VDR independent actions also protect them from these diseases just as they appear to do after puberty for intestinal calcium absorption?

## 9.4 Asthma in HVDRR patients

VDR and  $1\alpha$ -hydroxylase (*CYP27B1*) are expressed in immune system cells as well as in respiratory tract epithelial cells [241,242]. The local extrarenal production of  $1,25(\text{OH})_2\text{D}$  in the presence of functional VDR enables intracrine/paracrine actions of vitamin D in the immune system as well as in respiratory tract epithelial

cells [241]. Bar-Yoseph et al. [243] studied the role of the VDR in lung function, in airways and systemic markers of inflammation, as well as in allergy, among HVDRR patients. Those patients failed to generate airway hyperactivity responses following methacholine challenge test, similar to *Vdr* knockout mice that failed to generate airway hyperactivity responses [244]. The findings suggest that the VDR is required for the generation of cytokines involved in the hyperactivity response and lung inflammation. The exhaled breath condensate cytokine profile in HVDRR patients showed significantly higher IL-4 and IL-17 concentrations compared to controls, while IL-5, IL-10, and interferon- $\gamma$  concentrations were significantly lower. The results obtained from the HVDRR patients suggest that although the pro-inflammatory cytokines IL-4 and IL-17 are elevated, the recruitment of other immunological factors is needed for the escalation of the asthmatic cascade. None of this group of HVDRR subjects has developed asthma. The potential contribution of vitamin D deficiency to the development of asthma is discussed in Chapter 107.

## 9.5 The cardiovascular system in HVDRR patients

Several studies have shown that the VDR in adult rat and mouse cardiomyocytes is located in the t-tubular structure [245]. Ablation of the VDR in mice resulted in chronic changes in contractile kinetics: specifically, 1,25(OH) $_2$ D had rapid effects on myocyte contraction that were absent in *Vdr* knockout myocytes [245]. It was proposed that calcitriol (1,25(OH) $_2$ D) acts directly on the heart as a tranquilizer by blunting cardiomyocyte hypertrophy [246]. Based on those observations, Tiosano et al. [247] studied the renin-angiotensin system, the blood pressure levels, and the cardiac structure of 17 HVDRR patients (9 male and 8 female). All patients had normal blood pressure measurements during ambulatory blood pressure monitoring. Furthermore, none had blunted nocturnal dipping during normal night sleep ("nondipper profile"), which, if dipping is present, is an early and sensitive sign of a general tendency toward hypertension. None of the HVDRR patients had any evidence of increased renin-angiotensin system activity or pathological hypertrophy of the heart, at least prior to the age of 36 years. These findings indicated that from 6 to 36 years of age, humans with HVDRR have normal renin and angiotensin-converting enzyme (ACE) activity, mild but nonsignificant elevation of angiotensin II, normal aldosterone levels, and no hypertension or gross cardiac abnormalities. The effects of vitamin D on the renin-angiotensin system are discussed in detail in Chapter 41, effects on

hypertension and cardiovascular disease are discussed in Chapter 78.

## 9.6 Reproductive history of HVDRR patients

VDR is expressed throughout the organs of reproduction, including oocytes, theca and granulosa cells, endometrium, and placenta in females, whereas in males VDR is found in Leyding cells, germ cells, mature spermatozoa, epididymis, and prostate suggesting a direct role for vitamin D in reproduction (Chapters 39 and 40).

Tiosano and Weisman [248] studied the reproductive history of 16 HVDRR patients (4 married men, 2 married women, 7 single women, and 3 single men). The subjects all had normal calcium and phosphorous levels either with or without modest calcium supplementation after reaching puberty. All of these HVDRR patients had normal pubertal development. The mean age at menarche of HVDRR women was  $13.8 \pm 0.8$  years and they all had normal and regular menstrual cycles. Two married women reported four pregnancies and they have four healthy babies born at term. The time to conceive in the HVDRR women was less than 1 year. Four married HVDRR men reported 15 pregnancies. Nine healthy babies were born. The time to conceive in the wives of the HVDRR men was less than 1 year. Semen analysis obtained from HVDRR men showed normal parameters including viscosity, PH, concentration, total count, motility, total motile count, vitality, and morphology. This study revealed that normocalcemic and normophosphatemic HVDRR patients have a normal reproductive history despite the lack of biologically active VDR. The study suggests that intact VDR is not crucial for reproduction and that the physiological role of normal VDR in reproduction of both men and women remains unclear.

## 10. Conclusions

HVDRR (VDDR-2A) is a rare recessive genetic disorder caused by heterogeneous mutations in the VDR that result in end-organ resistance to 1,25(OH) $_2$ D action. The classical role of 1,25(OH) $_2$ D is to regulate mineral homeostasis, achieved through its coordinated actions on the intestine, kidney, bone, and parathyroid gland. The major manifestation of the defective VDR on the vitamin D endocrine system is to decrease intestinal calcium and phosphate absorption that results in decreased bone mineralization and rickets. Secondary hyperparathyroidism follows as a consequence of the hypocalcemia and loss of feedback inhibition on PTH secretion, problems that cannot be overcome by the elevated levels of circulating 1,25(OH) $_2$ D.

The VDR is also expressed in a wide variety of normal and malignant tissues, including cells of mesenchymal and hematopoietic origin including the immune system [40,41,226–235]. From the ubiquitous nature of the VDR, it appears that the role of the VDR in cellular function is not simply homeostatic but rather pleiotropic. The expanded scope of vitamin D actions includes stimulation of differentiation, inhibition of cell proliferation, and modulation of the immune response in normal and malignant cells [4,227–235]. In addition, the regulation of cellular proliferation and differentiation by  $1,25(\text{OH})_2\text{D}$  is a common feature in many tissues that have been examined, and it is likely that this regulatory feature is a fundamental component of all biological responses to  $1,25(\text{OH})_2\text{D}$ . Notwithstanding the complexity and diversity of biological responses elicited by  $1,25(\text{OH})_2\text{D}$ , the profound skeletal abnormalities demonstrated in patients with HVDRR emphasize the fundamental and essential role of  $1,25(\text{OH})_2\text{D}$  in calcium homeostasis up until puberty, after which other factors subsume partially or completely the ability to regulate intestinal calcium absorption.

It is interesting to note that despite the many pleiotropic processes regulated by  $1,25(\text{OH})_2\text{D}$ , children with HVDRR exhibit only symptoms that relate to their calcium deficiency and alopecia if they have it. After normalization of calcium, they appear normal in most respects except for alopecia, when present, and after puberty, many no longer require calcium supplements. Analysis of HVDRR patients has provided many interesting insights into vitamin D physiology and the role of the VDR in mediating  $1,25(\text{OH})_2\text{D}$  action. However, the potential lack of an impact of loss of normal  $1,25(\text{OH})_2\text{D}$  actions in the young adult HVDRR population on the many diseases described in this book, such as cancer, diabetes, hypertension, autoimmune disease, etc., is as yet not fully understood. It should be kept in mind that the number of HVDRR subjects being followed is very limited, still mostly young, and over time more health problems may become apparent. However, at this time, the relative normalization of the general health of the HVDRR-affected subjects after puberty represents a dilemma that is not yet explainable. All patients followed in this cohort have normal liver and kidney function, none have cancer, diabetes, hypertension, autoimmune disease, endocrine disease, or cardiovascular disease and they do not require treatment with any medication other than that some still require calcium. All of the married individuals have had normal reproduction with healthy babies at term [186,248].

Another somewhat confusing finding in the HVDRR population is that even the problems of reduced calcium absorption and rickets seem to abate after puberty. We have discussed a hypothesis to explain this finding by pointing out that fractional calcium absorption, which

is low in children with HVDRR, rises substantially after puberty. This has led to the hypothesis that the improvement is due to vitamin D and VDR-independent actions to improve calcium absorption and that the mediator of these actions is the rise in estrogens at puberty. Estrogens have been shown earlier to mediate GI calcium absorption by a vitamin D-independent action [203–206]. But boys also show improvement in calcium absorption and here the hypothesis falls back on the presence of aromatase in the human GI tract [207] allowing for the local conversion of androgen precursors to estrogens in males with HVDRR to also improve calcium absorption via estrogenic action in postpuberty males. Thus, these data suggest that a vitamin D and VDR-independent mechanism can ameliorate the clinical difficulty caused by a mutation in the VDR that genetically inactivates vitamin D-dependant pathways.

Of all of the clinical findings in HVDRR-affected individuals, the major one that seems permanent is alopecia, in the affected persons that have it. Alopecia appears to be due to selective defects in the unliganded VDR protein and it is unrelated to the vitamin D molecule and its absence or deficiency. Alopecia is not seen in nutritional vitamin D deficiency or mutational defects in synthesis (VDDR-1s) or accelerated degradation (VDDR-3). Patients with DBD mutations and premature stop mutations in the VDR all have alopecia and are totally hormone-resistant. Based on which mutations cause alopecia and which ones do not, we concluded that mutations that affect DNA binding, VDR-RXR heterodimerization, or that truncate these critical regions of the VDR are all linked to alopecia while mutations that affect only ligand binding or possibly some coactivator binding functions are not. Some selective mutations that affect coactivator binding are also associated with alopecia. This indicates that VDR-RXR heterodimerization and DNA binding are critical for VDR function in hair development. A role for RXR is clearly demonstrated since targeted inactivation of RXR $\alpha$  in keratinocytes also causes alopecia [218].

In conclusion, the biochemical and genetic analysis of the VDR in HVDRR (VDDR-2A) patients has yielded important insights into the structure and function of the VDR in mediating  $1,25(\text{OH})_2\text{D}$  action. Mouse models of HVDRR created by inactivating or deleting the VDR have proved valuable adjuncts to the study of human HVDRR. Studies of the affected children with HVDRR continue to provide further insight into the biological role of  $1,25(\text{OH})_2\text{D}$  in vivo. However, the findings that many young adults with HVDRR, essentially a human VDR knock-out, are functioning normally without apparent abnormality or disease, raises important and difficult questions about extra-skeletal vitamin D actions throughout the body for which there is a growing body of evidence as detailed in many chapters in this book. As

in the example of improved GI calcium absorption after puberty leading to a cure of rickets, alternative vitamin D and VDR independent actions may also play a role in attempting to normalize the biology in the population with an inactive VDR, as such a mechanism mediated by estrogens appears to do in HVDRR affected children after puberty.

A concerted investigative approach of HVDRR at the clinical, cellular, and molecular levels and useful animal models has proven exceedingly valuable in understanding the details of the mechanism of action of 1,25(OH)<sub>2</sub>D and the role of the VDR. The research has also improved the diagnostic and clinical management of this rare genetic disease. But several critical issues remain to be resolved including the role of vitamin D and the VDR, in many common and serious extra-skeletal diseases associated with vitamin D deficiency.

### 11. Summary points

- HVDRR is caused by heterogenous mutations in the VDR.
- The affected children develop severe rickets, hypocalcemia and secondary hyperparathyroidism due to loss of vitamin D action to increase intestinal calcium absorption.
- Therapy is targeted at replacing the deficient calcium with large supplements either intravenous or oral. The use of Cinacalcet to reduce hyperparathyroidism has proven useful as a therapeutic adjunct and appears to reduce the need for intravenous delivery of calcium.
- Restoring calcium to normal with supplements leads to curing of the rickets suggesting that the major benefit of vitamin D action on bone occurs in the GI tract on the calcium absorption pathway.
- Many children exhibit spontaneous improvement of rickets around the time of puberty and some no longer need calcium supplements to maintain adequate calcium levels. The current data indicate the improvement is due to the pubertal increase in estrogens that mediate a vitamin D-independent action to increase intestinal calcium absorption. Males also improve because of aromatase enzyme activity within the GI tract to convert androgens to estrogens.
- A small group of affected children and adults have been followed to determine whether they exhibit an increased risk of developing extra-skeletal diseases like cancer and autoimmune disease that are being studied to determine whether vitamin D deficiency increases the risk and worsens the prognosis. At this time, the small number of subjects and mostly young

adults do not show evidence of increased risk of any disease and appear to have normal reproduction.
